Mm^3	million cubic metres

GLOSSARY

Aggradation	Increase in channel bed elevation due to the deposition of sediment. Aggradation occurs in areas in which the supply of sediment is greater than the amount of material that the system is able to transport. Opposite to degradation.
Angle of Repose	Steepest angle, relative to the horizontal plane, at which a granular material will come to rest when added a pile of similar material.
Antecedent Conditions	Conditions that existed at a site prior to an event under consideration.
Avulsion	The formation of a new stream channel. Avulsions typically occur during flood events.
Bankfull Depth	Average flow depth at bankfull discharge.
Bankfull Discharge	Discharge that occurs just before water flows out of a channel and onto the surrounding floodplain in a vertically stable channel. Bankfull discharge is the dominant channel forming flow that is exceeded on average every 1 – 2 years.
Bankfull Width	Channel width at bankfull discharge.
Blanket	Surface expression characteristic used in terrain mapping to differentiate thickness of surface material greater than 1 m.
Braided	Channel pattern resembling hair braid, consisting of small channels separated by bars that divide and rejoin at low flows.
Channel	The bed and banks of a stream, whether or not it usually contains water. Channels are linear depressions through which water and sediment is conveyed through a watershed.
Debris	Soil that contains a significant portion of coarse material; 20% to 80% inorganic particles greater than 2 mm, and the remainder less than 2 mm.
Debris Fall	Detachment of debris from a steep slope or river bank. Material is transported through the air by falling, rolling, or bouncing.
Debris Flood	Hyper-concentrated sediment flow that is transitional between a debris flow and a purely hydrologic flood.
Debris Flow	A debris flow is a very rapid to extremely rapid mass movement (typically greater than 5 m/s) of saturated non-plastic debris in a channel. Debris flows normally have volumetric sediment concentrations of 50-90%. In this report, we utilize the term debris flow to describe the rapid to extremely rapid surges of fine grain tailings and native material that travelled down Hazeltine Creek Channel following the tailings storage facility failure on August 4, 2014.
Degradation	The process by which a channel down cuts due to erosion of sediment from the stream bed.

GLOSSARY (Cont'd)

Delta	A fan-shaped deposit of sediments occurring where a stream meets standing water.
Deltaic Deposits	Sediment deposited within a delta by a river.
Deposition	The process by which transported sediment, soil, and rock comes to rest. Deposition occurs when the force of transportation is overcome by the forces of friction and gravity.
Digital Elevation Model (DEM)	The most common digital representation of the shape of the earth's surface. A DEM uses a network of cells, each with a single elevation value, to create a continuous topographic surface.
Displaced Material	Material removed from its original position by erosion processes.
Entrenched	Vertically incised, relatively narrow channel that is hydrologically disconnected from the floodplain.
Erosion	Geomorphic processes (excluding weathering and mass movement) that involve the removal and entrainment of material or rock by an erosive force. Includes vertical and lateral removal of material from a river bed, channel banks and floodplain.
Fall	Detachment of soil or rock from a steep slope or river bank. Falling describes a process where there is effectively no shear displacement along the failure surface and where material is transported through the air by falling, rolling, or bouncing.
Floodplain	Floodplains are generally broad, gently sloped valley floors that provide a spatial link between the river and the surrounding lands. They form through deposition of sediment within the channel during channel migration and deposition over the channel bank during floods.
Frost Heave	The uneven lifting or upward movement, and general distortion, of surface soils, rocks, vegetation, and structures such as pavements, due to subsurface freezing of water and growth.
Frost Jacking	Frost jacking is the upward movement of improperly anchored surface structures as a result of frost heaving.
Glacial Till (Moraine)	Sediment deposited directly by or from a glacier with little to no reworking by water. Till deposits are typically diamictons, consisting of large clasts set within a fine grained matrix of silt and clay.
Gully Erosion	Entrainment and transport of soil material by water resulting in the enlargement of a gully. Gullies are ephemeral channels deeper than 30 cm occurring where flows concentrate to cut a channel through erodible soil. Gullies are relatively deeper and narrower than stream channels, with steep sidewalls and steep channel slopes.

GLOSSARY (Cont'd)

Hysteresis	Hysteresis occurs when the relationship between discharge and suspended sediment concentration or turbidity values change through a hydrograph. A common pattern is created when the suspended sediment concentration or turbidity values are higher during the rising limb of a storm hydrograph than the falling limb for a given discharge, forming the shape of a loop on the plot of discharge and suspended sediment or turbidity.
Incising	Process of a channel eroding vertically into its bed.
Knickpoint	A short over-steepened segment of the longitudinal profile of a river caused by the headward erosion of a resistant layer in the river bed. Knickpoints migrate upstream with time.
Lacustrine Deposits	Sediments that have settled from suspension in bodies of standing freshwater, or sediments that have accumulated at their margins through the action of waves. Lacustrine deposits are typically fine grained, consisting of stratified sands, silts, and clays. Glaciolacustrine deposits result from similar processes in ice-dammed lakes, and share many characteristics with lacustrine deposits.
LiDAR	Light Detection and Ranging (LiDAR) is a remote sensing technology which determines the range of an object by measuring the time delay between the transmission of a laser pulse and detection of the reflected signal. LiDAR sensors are commonly aircraft-mounted, and used to acquire high resolution data of the Earth's topographic surface.
Native Material	Native material refers to the soils, surficial deposits, and bedrock that were present in the study area prior to the event.
Nival Hydrologic Regime	Hydrological system that is dominated by snow melt.
Peak Stage	Highest elevation that the surface of a flow attains during a flood or debris flow.
Planform	Pattern a river channel makes on a map or aerial photograph. River planforms include braided, meandering, straight, wandering, and anastomosed.
Reach	Any length of the channel similar in hydrological and/or geomorphological characteristics.
Remobilize	Entrainment of a particle following deposition.
Retrogression	Slope failure in which the surface of rupture propagates upslope.
Riffle-Pool Morphology	Riffle-pools are channels characterized by a sequence of bars, pools, and riffles. Pools are topographic low points within the longitudinal profile of the channel, while riffles are topographic high points. Riffle-pool channels occur at moderate to low gradients, and are generally unconfined with well developed floodplains.

GLOSSARY (Cont'd)

Rill Erosion	Rills are shallow drainage channels from 50 mm and 300 mm in width and up to 300 mm in depth. They develop when runoff concentrates in depressions or low points and erodes the soil.
Scour	Vertical erosion of the river bed and floodplain.
Shear Stress	A force produced by water flowing at the bed of the channel.
Sinuosity	Measure of the total length of a channel, where channel length increases with number and size of bends. Sinuosity Index (SI) is calculated by dividing the main channel length by the valley length.
Slope Failure	Movement of a mass of soil, rock or debris down a slope.
Soil (earth)	Material that contains more than 80% of inorganic particles smaller than 2 mm.
Soil/Earth Fall	Detachment of soil (earth) from a steep slope or river bank. Material is transported through the air by falling, rolling, or bouncing.
Step-Pool morphology	Step-pool channels are characterized by steps made up of large rocks that span the channel alternating with pools containing finer material. Step-pool channels develop on steep gradients, are generally narrow and deep, and confined by valley sides.
Storativity	Dimensionless quantity, and ranges between 0 and the effective porosity of the aquifer.
Tailings	Fine-grained, residual materials remaining after valuable resources have been extracted from the ore at a mineral processing plant (CDA, 2007).
Terrace	Horizontal fragments of floodplains recorded in the landscape above the modern floodplain. Terraces are created by the incision (downcutting) of a stream channel, leaving the former floodplain level(s) higher than the modern floodplain.
Thalweg	The deepest part of a channel formed by joining the lowest points along the length of a waterway. The thalweg is almost always the line of fastest flow in a watercourse.
Topple	Forward rotation, out of the slope, of a block of soil/rock, about a point or axis below the centre of gravity of the displaced mass (Couture, 2011).
Veneer	Surface expression characteristic used in terrain mapping to differentiate thickness of surface material less than 1 m.

1 INTRODUCTION

SNC-Lavalin was retained to prepare a hydrotechnical and geomorphological assessment of impacts to Hazeltine Creek following the Tailings Storage Facility (TSF) dam failure (event) at Mount Polley Mine (Mine) on August 4, 2014. This report describes the impacts of the TSF dam failure between Polley Lake and Quesnel Lake, including impacted areas of Hazeltine Creek and Lower Edney Creek. Both immediate physical impacts from the failure and potential long-term effects on sediment production and channel morphology were considered. Herein we report on the hydrological characteristics of Hazeltine Creek and the pre-and post-event channel and floodplain geomorphology, and identify areas of concern for future erosion and bank failures within the study area. This report is a technical appendix to the Post-Event Environmental Impact Assessment Report (PEEIAR) authored by Golder Associates Ltd. (Golder) on behalf of Mount Polley Mining Corporation (MPMC).

1.1 Scope

The work described herein was conducted in general accordance with Chapter II of SNC-Lavalin's proposal, *Mount Polley Comprehensive Environmental Impact Assessment Work Plan* (August 29, 2014). The scope of the assessment included:

1) A gap analysis to determine data requirements for Hazeltine Creek[1];
2) An update of the regional hydrological analysis;
3) Monitoring of Hazeltine and Edney Creeks post-event discharge;
4) Determination of pre-event geomorphology of Hazeltine Creek through analysis of historical data and channel time-series mapping;
5) Determination of post-event geomorphology of Hazeltine Creek through field observations and channel mapping;
6) Determination of the volume of material eroded from the channel and floodplain;
7) Determination of the volume of material deposited on the channel and floodplain;
8) A characterization of surficial material; and,
9) An analysis of the hydraulic patterns of Hazeltine Creek following the debris flow.[1]

[1] The gap analysis is not explicitly reported on but was used to inform the analyses included in the assessment.

1.2 Report Structure

The report uses three main sections to document the impacts of the TSF dam failure on the geomorphology of Hazeltine and Edney Creeks. The first section summarizes the hydrology of Hazeltine Creek and includes an update to the regional flood frequency and presentation of post-event discharge and turbidity recorded at hydrometric stations. The second section documents pre-event geomorphology of Hazeltine and Edney Creeks using previous reports and mapping of the channels from historical aerial photographs. The reaches defined by Minnow Environmental Ltd. (Minnow, 2007) are used to define the pre-event channel characteristics. The third section documents the post-event geomorphology of Hazeltine and Edney Creeks based on a field program, analysis of the post-event LiDAR derived digital elevation model (DEM), and aerial and field photographs. The reaches defined by Minnow (2007) were modified and used to document the geomorphology of Hazeltine and Edney Creek channels. The third section utilizes hydraulic model results and the post-event DEM to define areas within the channel that are unstable and to assess the stability of the slopes within the valley.

The appendix section represents an atlas that documents the physical impacts of the debris flows on Hazeltine and Edney Creeks. The maps and photographs within the appendices are used to document the impacts of the debris flows and locate them spatially. Appendix A provides maps of the area affected by the debris flow and the locations of the reaches used in the analysis. Appendix B provides maps of the geomorphic characteristics of the pre-event channel. Appendix C provides cross-sections and photographs of the pre-event channel reaches. Appendix D provides maps of the estimated volumes of material eroded from the Hazeltine Creek valley. Appendix E provides maps of the estimated volumes of material deposited within the Hazeltine Creek valley and includes the surficial material types. Appendix F provides maps of the depth, velocity and shear stress results from a 2D hydrodynamic model for an average (mean annual flood), moderate (10-year) and large (100-year) flow in the post-event channel. Appendix G provides maps of the results of the slope stability analysis. Appendix H provides cross-sections and photographs of the post-event channel reaches.

1.3 Study Area

The study area follows the flow path of the debris flow from the TSF dam failure site to Polley Lake and down the Hazeltine Creek valley to Quesnel Lake. The width of the study area ranges from 23 m within the canyon to 1 km in Lower Hazeltine Creek. The study area is sub-divided into five sub-areas based on morphology and characteristics: the Plug area, Upper Hazeltine Creek, Hazeltine Creek Canyon, Lower Hazeltine Creek and Edney Creek.

2 HYDROLOGY OF HAZELTINE CREEK

Hazeltine Creek is a tributary stream within the Quesnel River Watershed in the Cariboo Plateau, south-central British Columbia. This region is characterized by low hills and broad valleys (Cathro et al., 2003). Prior to the event, Hazeltine Creek was the main outlet of Polley Lake, flowing from its south end at 920 masl (Knight Piesold Ltd, 2009c). The creek flowed 10.3 km, draining an area of 112 km^2 (Minnow, 2014a) into Quesnel Lake at an elevation of 730 masl (Knight Piesold Ltd., 2009c). Bootjack and Edney Creek supply surface water to Hazeltine Creek. The confluence with Edney Creek was located 9.5 km downstream of the Polley Lake outlet, adding 81.3 km^2 of drainage basin area (Minnow, 2014b) into the channel before being discharged into Quesnel Lake (Figure 1). The confluence with Bootjack Creek was located 850 m downstream of the Polley Lake outlet, adding 2.74 km^2 of drainage basin area (Minnow, 2014b).

Streams in the Cariboo Plateau follow a nival hydrologic regime driven by spring snowmelt. Regional average monthly climate data from 1989 to 2006 (Horsefly Lake / Gruhs Lake, Climate Station 1093600[2]) are presented in Figure 2-1. Snow is the dominant form of precipitation from mid-September through to late April (based on Horsefly weather station data) and remains in storage within the drainage basin until spring melt. As a result, streams of this region experience low flows throughout the winter and peak flows during the spring months as warmer temperatures induce snowmelt. Precipitation falls almost entirely as rain for the rest of the year and contributes directly to stream flow as well as indirectly through rain-on-snow melting events. Low precipitation amounts through the late summer and early fall combined with an exhausted snowpack result in seasonal low flow conditions.

The historical hydrologic regime of Hazeltine Creek was altered as a result of water diversions for placer mining. A water diversion ditch was dug in the late 1890's (Mulvihill *et al*., 2005) to channel water from Polley Lake to the Bullion Pit for hydraulic mining. Bootjack Lake originally drained into Hazeltine Creek via Bootjack Creek until an earthen dam was erected in 1913 and lake water was diverted to Moorhead Creek (IMC, 1990). This resulted in the loss of 14 km^2 of drainage area input into Hazeltine Creek. Construction of runoff collection ditches at the mine site has also influenced the watershed area (Minnow, 2014b).

Conifer species are the dominant vegetation within the floodplain, with an abundant shrub and moss layer below the closed coniferous canopy (Lord, 1984). There are potential impacts on Hazeltine Creek from grazing on Crown range land and private farmland, and forest harvesting and subsequent replanting (IMC, 1990). Studies of the direct effects of logging and cattle grazing on the hydrology of Hazeltine or Edney Creeks were not found during the gap analysis. However, Hazeltine Creek is highly impacted by logging (DFO, 1990). Large areas (42%) of the Hazeltine

[2] Data from climate.weather.gc.ca

Creek drainage basin were logged (Rood and Hamilton, 1995) and the high percentage of cut has resulted in sedimentation and extreme water temperature fluctuations within the creek (Rowland and MacDonald, 1996). Nener and Wernick (2000) indicated that livestock grazing may have caused some impacts to Edney Creek watershed and large areas (45%) of the Edney Creek drainage basin have been logged (Rood and Hamilton, 1995).

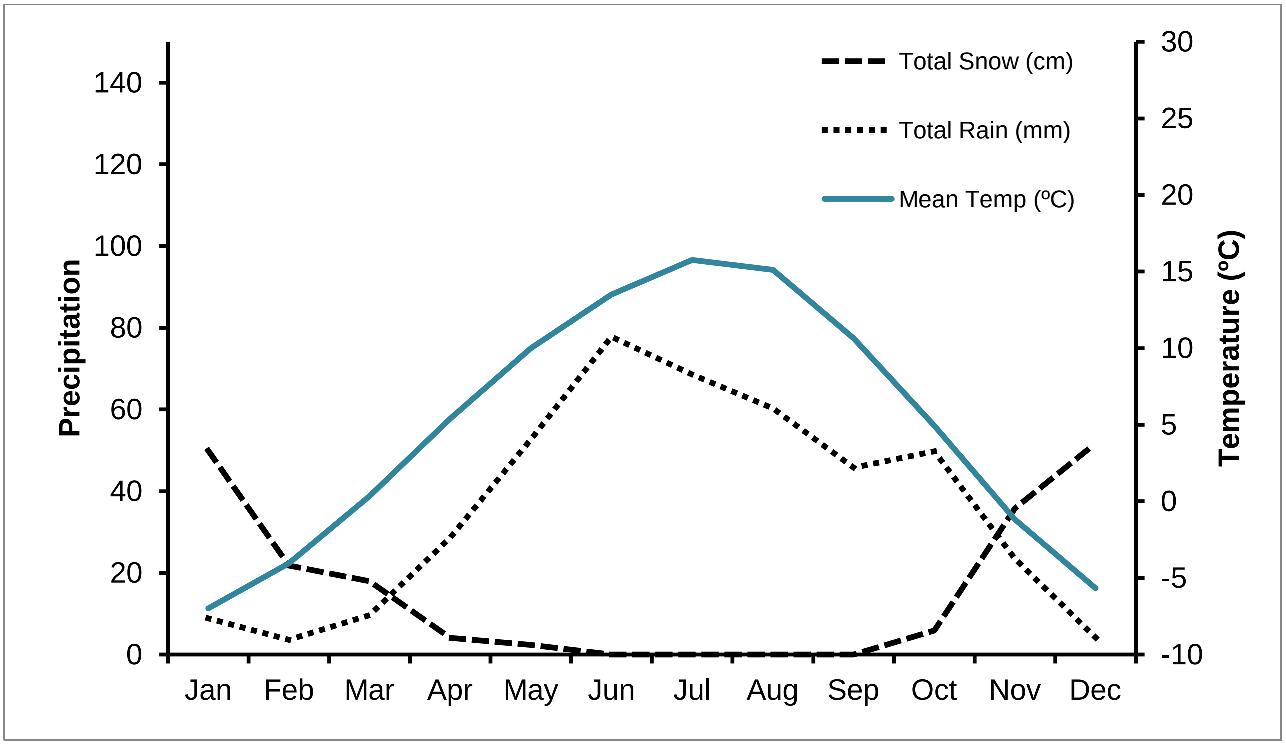

Figure 2-1: Mean monthly precipitation and temperatures for the Horsefly Lake/ Gruhs Lake weather station

2.1 Hydrometric Stations

Stream flow data has been collected on Hazeltine Creek since 1994 at a hydrometric station located at the Gavin Lake road bridge (Figure 2-2). The hydrometric station was installed and operated by Water Survey of Canada (WSC) until 1995 (08KH027), when MPMC assumed operation and maintenance of the station. The catchment area for the Upper Hazeltine Creek station was 24.3 km^2 (Golder, 2015).

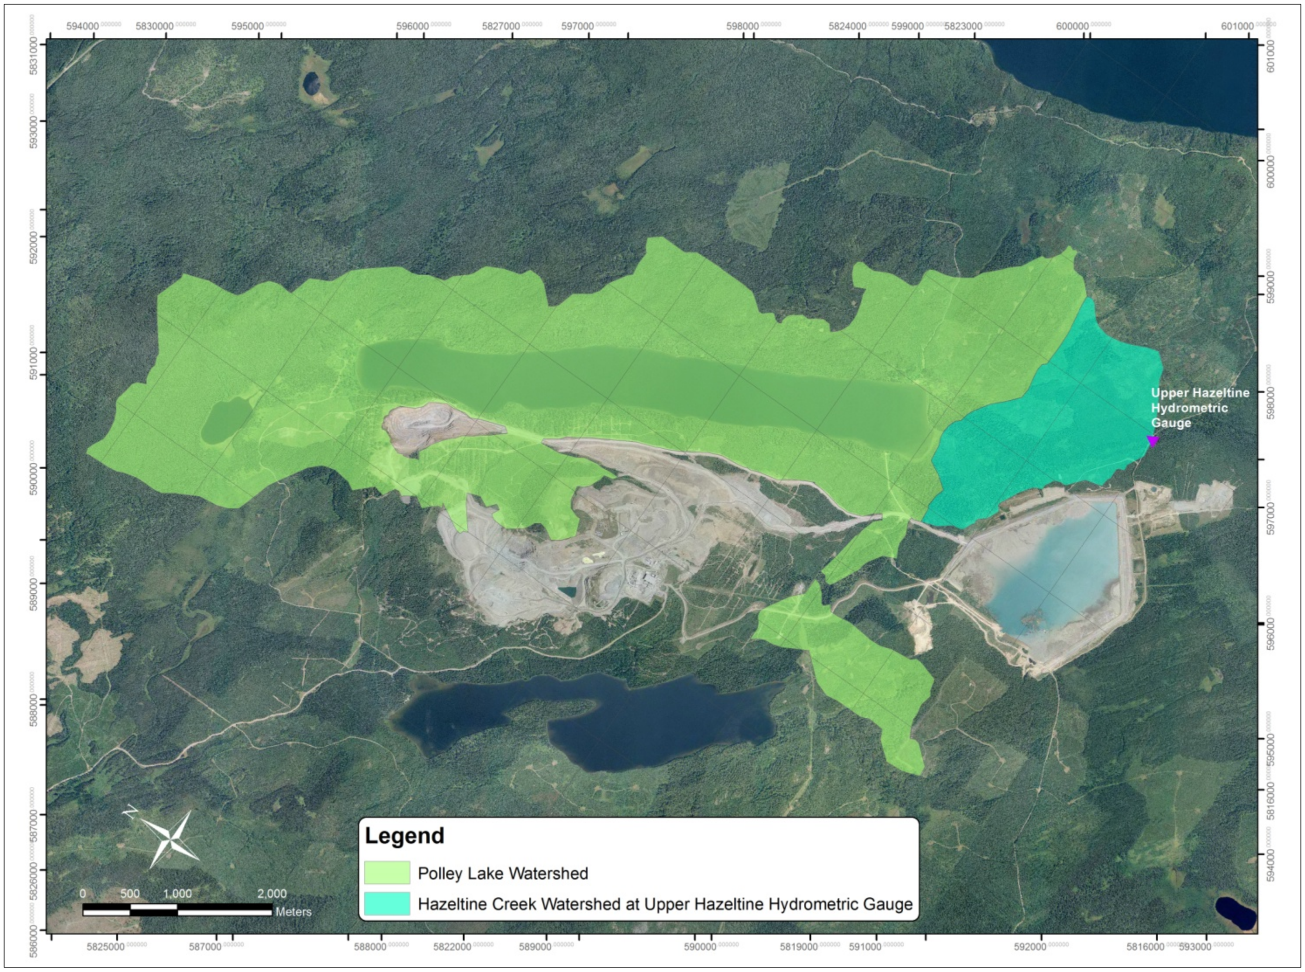

Figure 2-2: Map of the Hazeltine Creek Watershed above the Upper Hazeltine Creek hydrometric station. Modified from Golder 2015

Hazeltine Creek discharge was gauged between the onset of the annual freshet (usually April) and the occurrence of the first frost (usually October/November). The stage-discharge rating curve from data collected between 1994 and 2006 displayed distinctive shifts between years of record, likely due to frost jacking of the gauge staff. Knight Piésold (2009a) created a synthetic data series to correct the shifting of the dataset and to model the months when data were not collected on Hazeltine Creek through a regional analysis using a nearby watershed with similar characteristics (Moffat Creek, Water Survey of Canada Hydrometric Station 08KH019). This yielded an annual hydrograph (Figure 2-3) which began its ascent in mid-March, reaching a peak discharge of 0.74 m^3/s in early April, and with low flow conditions extending from mid-July to mid-March.

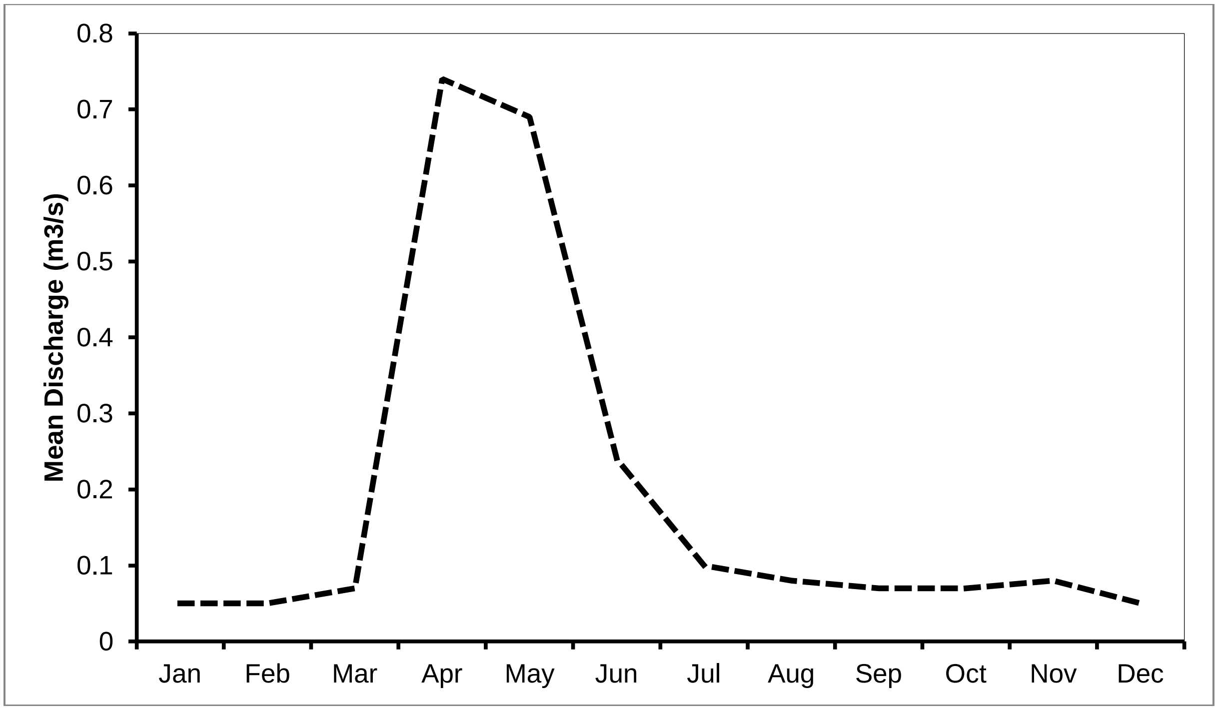

Figure 2-3: Annual hydrograph for Hazeltine Creek generated from synthetic dataset created by Knight Piésold (2009a)

The hydrometric station on Hazeltine Creek was destroyed by the TSF dam failure and subsequent flood in 2014, and replaced by three stations in November 2014: one at the previous location at the Gavin Lake Road bridge (Upper Hazeltine Creek), one in Lower Hazeltine Creek and one on Lower Edney Creek (see Table 2-1 for site details). Two of these stations were installed along the disturbed sections of Hazeltine Creek (Lower Hazeltine Creek Station and Upper Hazeltine Creek Station) and a third station was installed along an undisturbed section (Lower Edney Creek). The Lower Edney Creek station was impacted by construction of a beaver dam immediately downstream from the station shortly after installation and was re-established on March 5, 2015 along the disturbed section of Edney Creek following channel reconstruction.

Details regarding discharge monitoring program (i.e. station installation and benchmarking, station calibration, data processing, field records and recommendations for future monitoring) are provided in WaterSmith Research Inc. (2015).

At each station, a Solinst Level Logger (recording water level [i.e., stage] and temperature) was installed in the bottom of a stilling well. A Solinst Baro Logger (recording barometric pressure) was installed in the top of the stilling well at each Hazeltine station. All loggers were programmed to record data at 10-minute intervals. A staff gauge was installed adjacent to each stilling well.

Benchmark elevations were established at all hydrometric stations during installation, as recommended by the Resources Information Standards Committee (RISC) for hydrometric monitoring (BC Ministry of Environment, 2009). A local elevation datum was defined for each station at an elevation 1.00 m below the Level Logger port. The stations were surveyed by MPMC staff on March 11, 2015, to determine the absolute elevations (meters above sea level). Site schematics are provided in Figure 2-4.

Table 2-1: Measurement variables and location information for the hydrometric stations

Station name	Measurement variables	Channel characteristics	Hardware anchoring system	Universal Transverse Mercator (UTM) easting / northing	Elevation at logger port (m)[1]
Upper Hazeltine (Gavin Lake road bridge)	Stream discharge, barometric pressure, water temperature, turbidity	Shallow pool in riffle-pool alluvial reach (disturbed section)	Welded to bridge span	0596944 / 5819047	901.64
Lower Hazeltine	Stream discharge, barometric pressure, water temperature, turbidity	Shallow pool in bedrock controlled reach (disturbed section)	Bolted to bedrock	0600544 / 5817369	754.91
Lower Edney	Stream discharge, water temperature	Deep pond (reconstructed section)	Bolted to boulder	0601356 / 5817042	734.42

1. Elevation based on a GPS survey conducted by MPMC staff on March 11, 2015 using the TSF Grid.

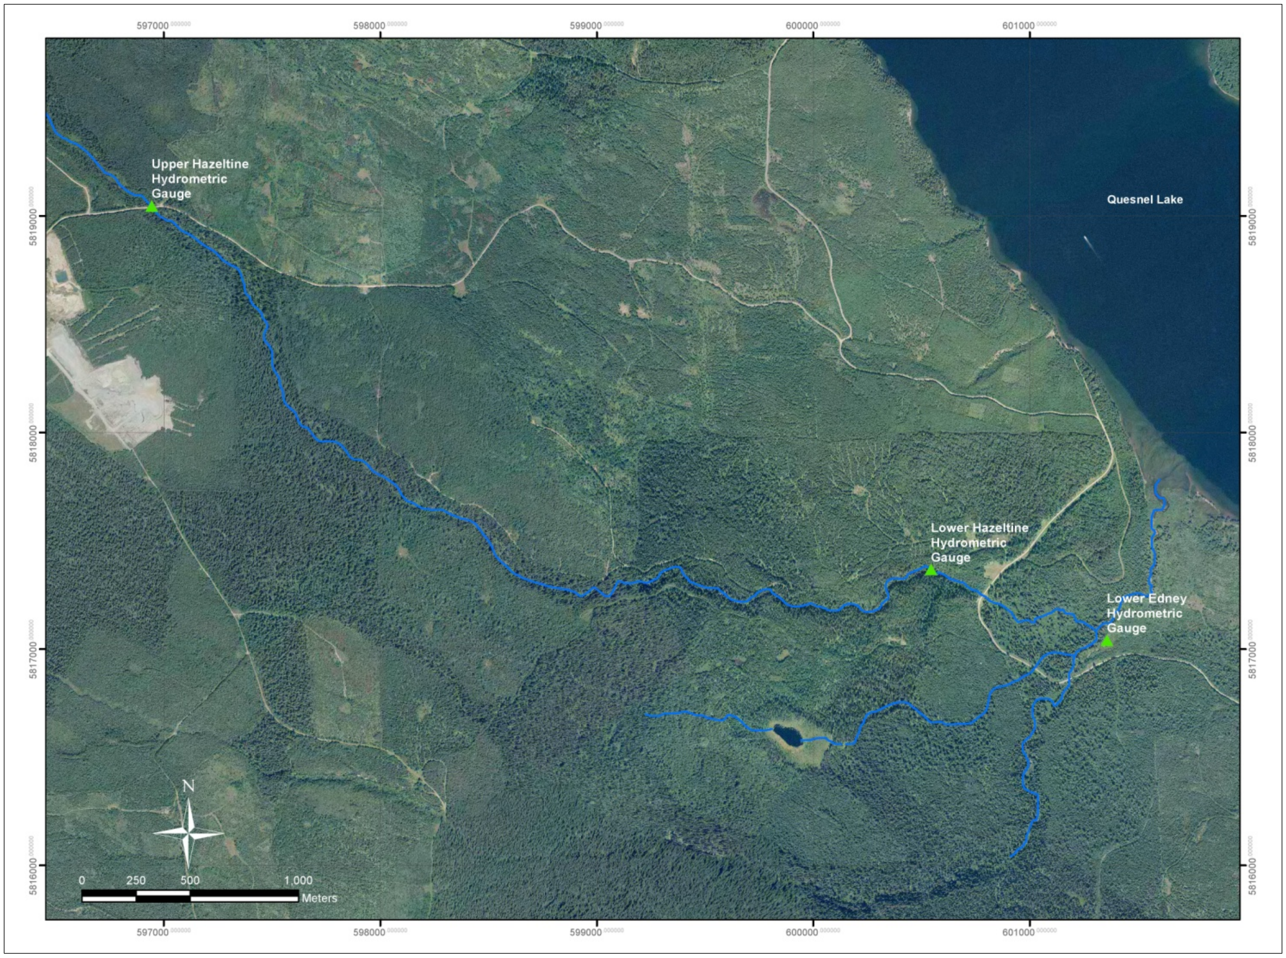

Figure 2-4: Location of current hydrometric gauges on Hazeltine and Edney Creeks

To record the temporal patterns in turbidity, Manta 2 automated turbidity probes were installed at the Upper and Lower Hazeltine hydrometric stations, allowing for comparison between sites. The probes were installed between November 5 and 7, 2014. The probes were encased in perforated steel pipes bolted to bedrock (Lower station) and the underside of a bridge span (Upper station). Prior to installation, the turbidity sensors were calibrated using deionized water (0 NTU) and a polymer turbidity standard (3000 NTU). The loggers were set to record turbidity and water temperature at 30-minute intervals.

The accuracy of the Manta 2 turbidity sensor is reported to be ±1% of the reading plus 1 NTU over the range of 0 to 400 NTU (e.g., at 50 NTU, the accuracy is ±1.5 NTU; at 400 NTU, the accuracy is ±5 NTU), and ±3% of the reading over the range of 400 to 3000 NTU. The accuracy at readings above 3000 NTU is unknown, of which there were 16 readings at the Lower Hazeltine Creek station and none at the Upper Hazeltine Creek station.

2.2 Regional Flow Frequency

Hazeltine Creek flows were estimated by a regional flood frequency analysis (Golder, 2015). Flow data from the pre-event Upper Hazeltine Creek station were of insufficient length and quality for flood frequency analysis. An assessment of regional stations (15) by Knight Piésold (2014) determined that flows derived from the Moffat Creek Water Survey of Canada hydrometric station (08KH019) provided an analog to estimate Hazeltine Creek flows based on catchment characteristics and hydrologic regime. A daily synthetic flow series was produced for Hazeltine Creek from the Moffat Creek record (47 years) using empirical frequency pairing (Knight Piésold, 2014). Results from this analysis are presented in Table 2-2 and include mean annual discharge (MAD), mean annual flood (MAF), mean 7-day low flow, and 10-, 100-, and 200-year discharges,.

Table 2-2: Flood frequency analysis for the Upper Hazeltine Creek Station (Golder, 2015)

Location	Catchment area (km^2)	Mean Annual Discharge (MAD) (m^3/s)	Mean 7-day low flow (m^3/s)	Mean Annual Flood (MAF) (m^3/s)	10-year (m^3/s)	100-year (m^3/s)	200-year (m^3/s)
Hazeltine Creek hydrometric station	24.3	0.19	0.016	1.6	2.5	3.7	4.0

2.3 Post-event discharge and turbidity from hydrometric stations

The record of discharge from the hydrometric stations is presented in Figure 2-5. Following the event the discharge of Hazeltine Creek was largely controlled by storm generated runoff and by water pumped by MPMC from Polley Lake into Hazeltine Creek.

The discharge record for the Upper Hazeltine Creek station is 5 days long, between the date of establishment (November 05, 2014 at 15:50) and the time when the record became unreliable (November 09, 2014 at 14:20). The short discharge record is due to changes in channel morphology shortly after installation of the Upper Hazeltine station that altered the stage rating curve used to determine discharge. The Upper Hazeltine station was established in a newly formed channel incised into exposed glacial till. Channel aggradation occurred at the hydrometric station during and after a rainfall runoff event on November 9, 2014. The data after November 9 were, thus, considered unreliable and were discarded (Figure 2-5). The record for Upper Hazeltine Creek shows changes in discharge due to pump operations upstream of the station and in response to rainfall events.

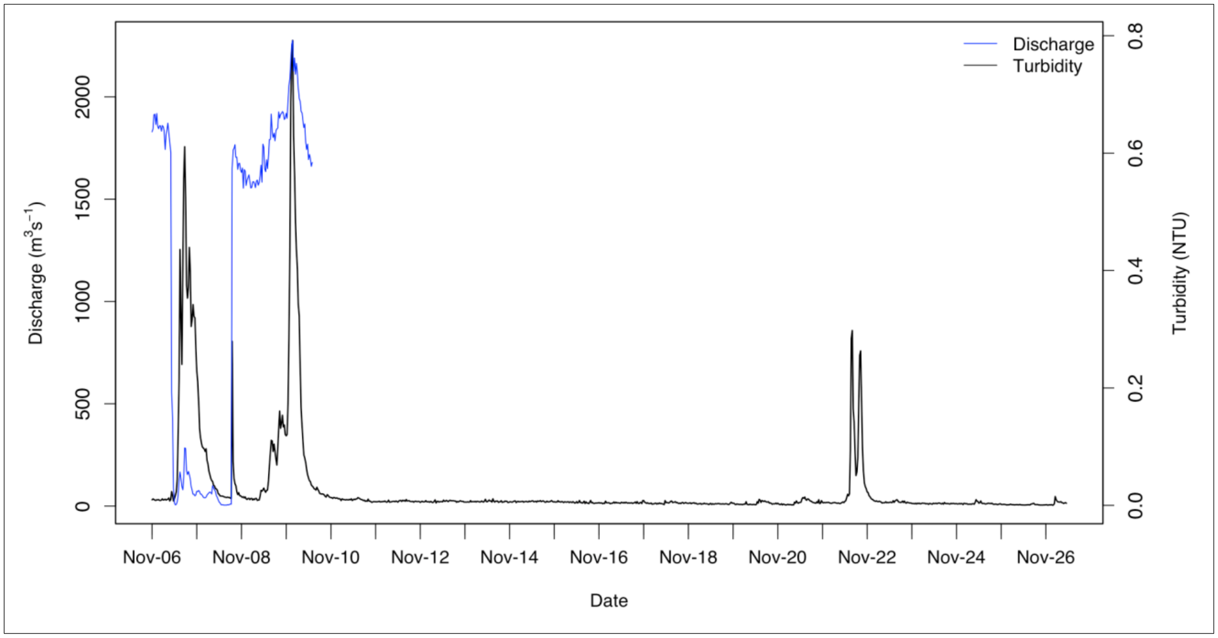

Figure 2-5: Turbidity and stream discharge time series plot for Upper Hazeltine Creek station

The discharge record for the Lower Hazeltine station is 99.6% complete, with only two minor gaps (< 1 day) between the date of establishment (October 09, 2014 at 14:20) and the most recent data download (March 04, 2015 at 14:10) (Figure 2-6). As with the upstream station the record for the Lower Hazeltine Creek station shows changes in discharge due to pump operations upstream of the station and rainfall events.

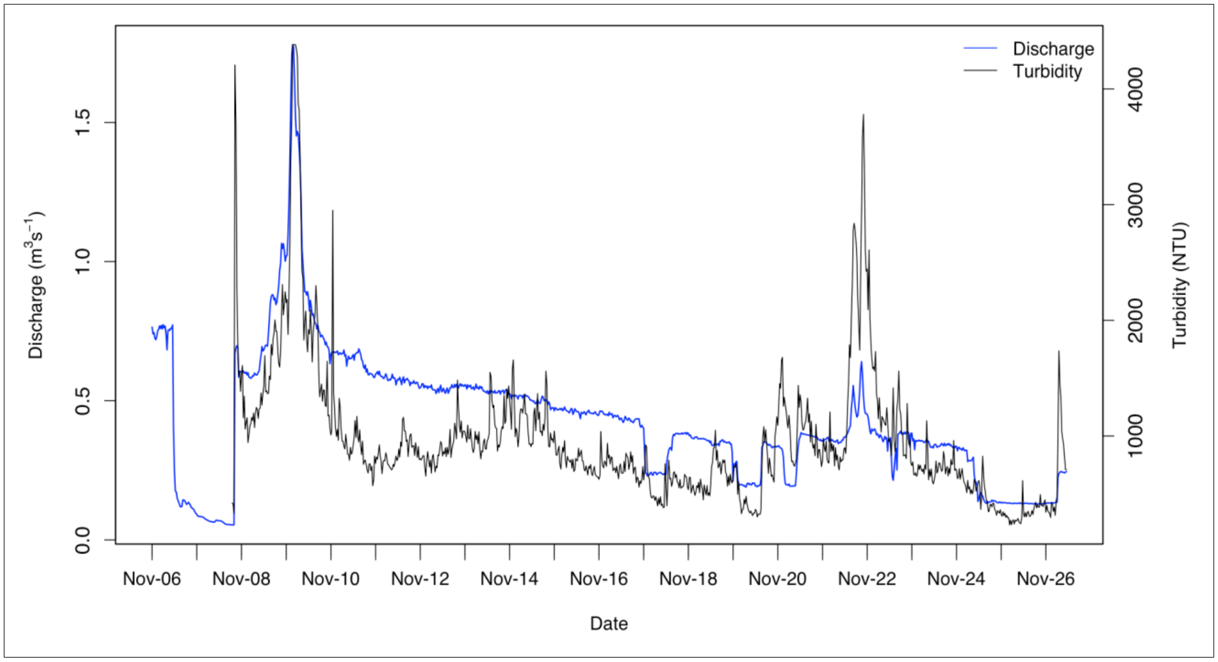

Figure 2-6: Turbidity and stream discharge time series plot for the Lower Hazeltine Creek station

The discharge record for Lower Edney Creek station became unreliable shortly after its initial installation due to beaver impacts along Edney Creek.

2.4 Post-event temporal turbidity patterns

Temporal patterns in suspended sediment were analyzed using the discharge and turbidity data collected at the two hydrometric stations on Hazeltine Creek. Patterns of turbidity against discharge were analyzed for storm events. This analysis provides evidence of areas where sediment is produced, the discharge conditions when sediment is produced, and indicates limits on sediment production.

The discharge and turbidity record for the two hydrometric stations on Hazeltine Creek, including colour coding for storm events, is presented in Figure 2-7 and Figure 2-8. Turbidity ranged from 4 to 2276 NTU at the Upper Hazeltine Creek station and 232 to 4383 NTU at the Lower Hazeltine Creek station, with median values of 21 and 828 NTU during the 22- and 20-day periods of record, respectively.

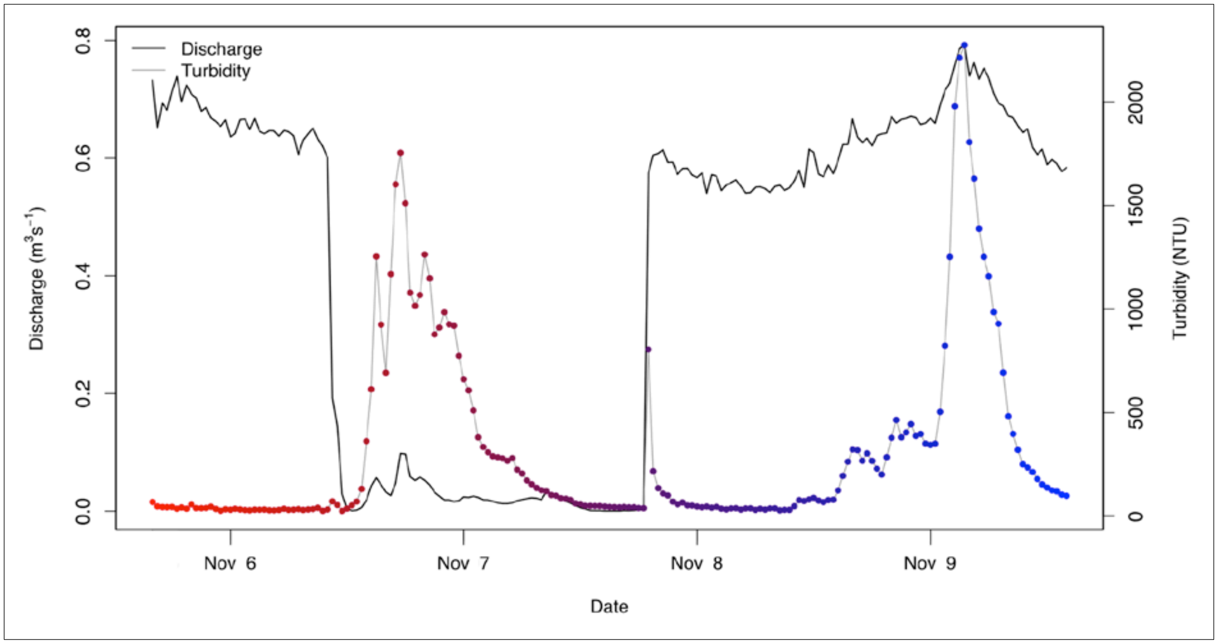

Figure 2-7: Turbidity and discharge time series plot for the Upper Hazeltine Creek Station per storm event

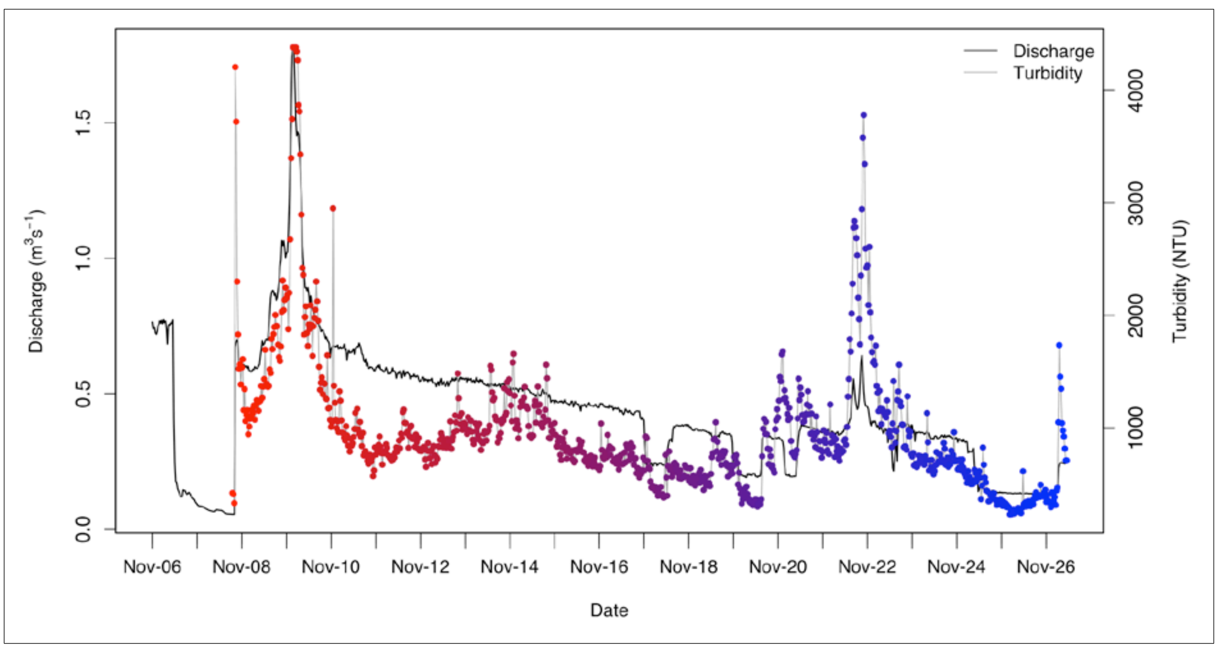

Figure 2-8: Turbidity and discharge time series plot for the Lower Hazeltine Creek station per storm event

Turbidity at the Lower Hazeltine Creek station was greater than at the Upper Hazeltine Creek station throughout the record (Figure 2-9). Turbidity ranged from 195 to 4100 NTU higher in the Lower station than the Upper station (with the exception of one measurement). Cumulative distributions of turbidity showed values remained under 38 NTU 80% percent of the time at the Upper Hazeltine Creek station, and under 1197 NTU 80% percent of the time at Lower Hazeltine Creek station (Figure 2-10). These results are consistent with observations made on the September 22, 2014 flight over Hazeltine Creek where the water was visibly less turbid near the Upper Hazeltine Creek hydrometric station (Figure 2-11) and more turbid downstream near the Lower Hazeltine Creek hydrometric station (Figure 2-12).

These results indicate that sediment in Hazeltine Creek is produced mainly in the ~ 4.7 km between the two hydrometric stations. The higher turbidity levels in Lower Hazeltine Creek (average value of 973 NTU) compared to Upper Hazeltine Creek (average value of 83 NTU) are likely related to (1) outflow from Polley Lake having relatively low turbidity, and (2) lower rates of sediment delivery to the channel within the upper ~ 2.2 km of Hazeltine Creek than within the ~ 4.7 km between the Upper and Lower stations. The channel between the Upper Hazeltine Creek hydrometric station and the upstream end of the Hazeltine Creek Canyon contains relatively steep channel gradients with active knickpoint erosion and steep valley sides. Sediment sources likely include a combination of tailings deposits, native material eroded through bed degradation, lateral bank erosion, and sloughing along the valley sides.

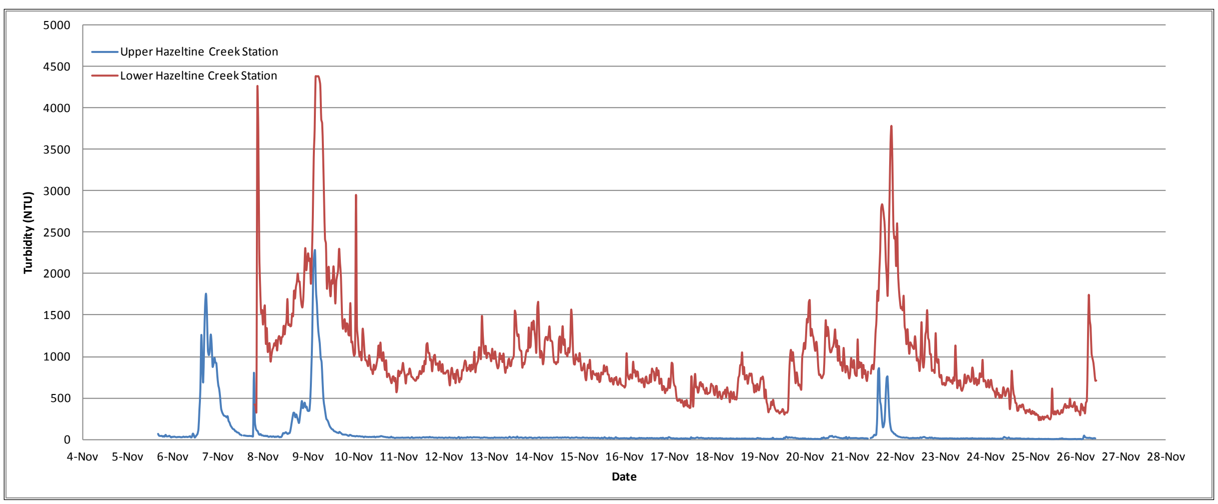

Figure 2-9: Turbidity for the Upper and Lower Hazeltine Creek stations in November 2014

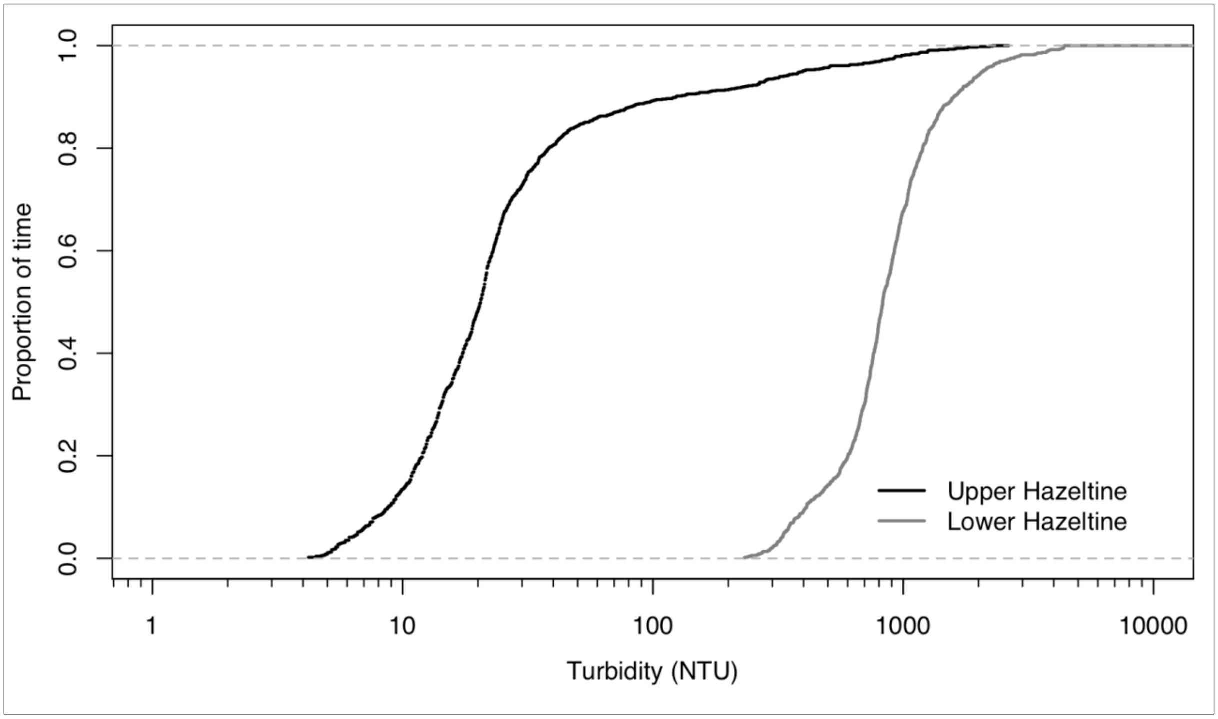

Figure 2-10: Cumulative distribution plot for Hazeltine Creek turbidity

Figure 2-11: Visibly less turbid water in channel upstream of the Upper Hazeltine Creek hydrometric station (September 23, 2014)

Figure 2-12: Visibly turbid water in channel downstream of the Lower Hazeltine Creek hydrometric station (September 23, 2014)

There is a positive relationship between turbidity and discharge seen in both records. The relationship is non-linear and highly dependent on antecedent conditions. Turbidity response is event specific, and likely a function of sediment availability, which is determined by the influx of new sediments into the channel and the storage of sediments within the channel during the days or hours preceding an event. For example, following a period of sustained low flow and deposition of suspended sediments within the channel, an initial increase in discharge will result in a rapid rise in turbidity as in-channel sediments are remobilized. This is followed by a decrease and potential stabilization in turbidity levels as the event progresses and the in-channel sediment source is depleted (Williams, 1989). For this reason, peak turbidity may occur prior to peak discharge resulting in hysteresis. This response behaviour is evident in the Lower Hazeltine data for events starting November 7, 21, and 26, 2014 (Figure 2-13). In contrast, the turbidity response to increasing discharge is more moderate after flows have already been elevated prior to an event, as evident in the Lower Hazeltine data for an event starting November 9 (Figure 2-14).

Notwithstanding the limited discharge dataset for the Upper Hazeltine site, the Upper and Lower Hazeltine sites both appear to have a lower limit of turbidity (Figure 2-15 and Figure 2-16). This minimum turbidity level is much lower at Upper Hazeltine station (~ 20-40 NTU for flows below 0.8 m^3/s) than at Lower Hazeltine station (~ 200-900 NTU for flows below 0.8 m^3/s). Moreover, the lower limit is clearly a function of discharge for the Lower Hazeltine site. After an initial rise in turbidity with increasing discharge, turbidity appears to stabilize above a minimum level that is controlled by the discharge rate.

These initial data suggest that the turbidity response at Upper Hazeltine Creek is higher for discharge increases caused by rainfall events than those caused by increased outflow (pumping) from Polley Lake. For instance, the November 7, 2014 pumping related event resulted in a lower turbidity response than the November 6 and 9, 2014 rainfall generated events, which had lower discharge increases (Figure 2-14, and Figure 2-15). The greater turbidity response associated with rainfall is likely related to mobilization of sediment within the disturbed areas adjacent to the channel, whereas outflow from Polley Lake would be capable of mobilizing only sediments stored within the channel. This difference in turbidity response behaviour elucidates the large potential of rainfall or runoff events to contribute sediment from adjacent areas within the TSF dam failure corridor.

3 CHANNEL AND FLOODPLAIN GEOMORPHOLOGY METHODS

3.1 Data Sources and Methods

3.1.1 Previous reports

Descriptions of the pre-event Hazeltine and Edney Creek watersheds were informed by published reports and datasets summarized below.

- Mount Polley Project - Stage I Environmental And Socioeconomic Impact Assessment. (Imc, 1990):
  - Impact assessment to support the proposed mine operation. The report includes a compilation of Hazeltine and Edney watershed characteristics, including descriptions of geology, climate and hydrology, water and sediment quality as well as projections of requirements for access, transportation and infrastructure and potential impacts of mine establishment and operation.
- Quesnel Habitat Management Area Resource Assessment, Volume 2. (Triton, 1991):
  - Provides a detailed assessment of historic, contemporary, and future impacts on fish habitat in the Quesnel Lake watershed due to the changing biophysical environment (including physiography, biogeoclimatic zones, precipitation, air temperature and hydrologic regime) and resource use (forestry, placer mining, hard rock mining, agriculture and recreation).
- Hydrology and Water Use for Salmons Streams in The Quesnel Lake Habitat Management Area, British Columbia. (Rood and Hamilton, 1995):
  - Describes the hydrologic and climatic regimes, surficial geology and soil characteristics of the Quesnel Lake Watershed. The report details the response of the regimes to land use activities (resource management and recreation) with an emphasis on salmon habitat sensitivity, as part of the Fraser River Action Plan.
- Salmon Watershed Planning Profiles for the Fraser River Basin within the Cariboo-Chilcotin Land Use Plan (CCLUP) Area. (Rowland and MacDonald, 1996).
  - Presents background information, including descriptions of the geographic and hydrologic regimes, as well as fish habitat management objectives for salmon bearing watersheds. Includes the Quesnel Lake Watershed within the Cariboo-Chilcotin region.
- Quesnel River study area - Fish habitat assessment procedure. (Pedersen, 1998):
  - Assessment of the fish habitat of Quesnel River watershed, identifying limiting factors in fish production and habitat restoration opportunities to improve fish stocks as part of a watershed restoration program.

- Aquatic environmental description report: Mount Polley mine discharge of treated water to Polley Lake. (Minnow, 2014a):
    - Documentation of biophysical conditions, water quality, sediment quality, fish communities, and sentinel fish populations in Hazeltine and Edney Creek Watersheds.
- Technical assessment report: Mount Polley Mine discharge of treated water to Polley Lake. (Minnow, 2014a):
    - Technical assessment to inform the release of accumulated surplus effluent from the Mount Polley Mine. The report outlines the permitting process, describes and provides a technical assessment for the proposed strategy, and outlines plans for mitigation, monitoring and contingency. Pre- and post-mine watershed areas described in this report were valuable to the current investigation.
- Hazeltine Creek habitat characterization. (Minnow, 2007):
    - Documents baseline channel characteristics (including channel widths, depths, slopes, bed and bank material and general morphology) and fish habitat features (functional instream cover and migration barriers) of Hazeltine Creek with a focus on salmonid spawning habitat.
- Recommended maximum discharges from the Mount Polley TSF to Hazeltine Creek. (Knight Piésold, 2009a):
    - Provides recommendation for maximum discharge in Hazeltine Creek with respect to effects on hydrologic regime, channel morphology, fish lifecycle and habitat suitability. Also considers acceptable rate of flow increase (flow ramping). The maximum acceptable discharge is set as a percentage of the creek's mean annual discharge (used as a proxy for formative discharge) based on month and uses fish habitat criteria outlined in Tennant (1976). Conducted to support MPMC's application for increase to allowable discharge of Mine waste-water.
- Hazeltine Creek Geomorphology - Regime modelling to predict changes in channel characteristics. (Knight Piésold, 2009b):
    - Provides prediction of relative changes to channel morphology in response to changes to discharge in Hazeltine Creek using a regime model developed by Eaton *et al.* (2004). Conducted to support MPMC's application to discharge of Mine effluent into Hazeltine Creek.
- Mount Polley Mine supplemental aquatic monitoring. (Minnow, 2012):
    - Physical, chemical, biological characterization of Hazeltine and Edney Creek to expand the dataset from the Minnow (2007) baseline report.

3.1.2 Historical aerial photographs

The pre-event location and dynamics of Hazeltine Creek channel were documented by mapping sequential historical aerial photographs (1974, 1996 and 2009). Aerial photographs were imported into the three-dimensional, heads-up mapping software DAT/EM® Summit Evolution™ and rectified to a base projection. The channel location and historical areas of erosion and deposition were digitized in 3D directly into ESRI® ArcMap™ for each year of aerial photographs. Three (3) historical aerial photographs of the site were used, captured at intervals of 22 and 13 years (Table 3-1). A summary of geomorphic feature classes used in mapping is provided in Table 3-2. Morphological change over time was interpreted qualitatively through comparison of features from one period to the next.

Table 3-1: Inventory of aerial photographs used in analysis

Date (Day/Month/Year)	Roll	Frame	Nominal Scale	Colour
10/08/1974	BC7600 BC7628	116-119, 147 – 152, 187-193, 218-223 014-017, 042-045	1:16,000	No
07/08/1996 09/08/1996 24/08/1996 10/08/1996 10/08/1996	30BCC 96073 30BCC96075 30BCC96109 30BCC96119 30BCC96120	045-050 160-164 043, 044 034-039 022-025	1:15,000	Yes
22/07/2009 23/07/2009	15BCC09021 15BCC09023	028-032, 122-127, 175-179 168-171, 204, 205	1:20,000	Yes

Table 3-2: Feature identification, code, and definition used for river channel mapping

Feature	Geomorphic Feature	Description
Channel	Main	Largest channel containing water with distinct banks; carries the majority of flow. Always active.
	Side	Channel containing water with distinct banks that carries a portion of the river discharge less than the main channel. Always active.
	Back	Channel containing water with distinct banks that is smaller than the main channel and connected to another channel at the outlet. Always active.
	Flood	Channel with distinct banks connected to a main or side channel only during flows at bankfull stage or greater.
	Cutoff channel	Dormant channel remnant(s). No longer directly connected to main flow (e.g., oxbow lake).
Bars	Lateral/point	Deposits of sand and/or gravel connected to the bank.

Table 3-2 (Cont'd): Feature identification, code, and definition used for river channel mapping

Feature	Geomorphic Feature	Description
Bars	Medial	Deposits of sand or gravel within the channel.
Other	Floodplain	Flat areas of overbank flow during flood events.
	Valley wall	Side slope of stream valley.
	Dominant Fan or Delta	Fan shaped deposit radiating from a point source and fed by an upstream drainage basin.
Activity	Active	Fluvial processes have acted on the channel or feature within 1 to 2 years from the date of remote imagery; features are considered active until vegetation is established.
	Dormant	Fluvial processes have not acted on the channel or feature within 2 years from the date of remote imagery; features are considered dormant when vegetation is established

Limitations of the interpretation of aerial photographs include:

- The scale and resolution of available aerial photographs; and
- Vegetative cover obscuring the channel and floodplain.

3.1.3 Digital Elevation Models (DEMs)

Three DEMs were available for analysis, including:

- A pre-event Terrain Resource Information Management (TRIM) DEM;
- A pre-event DEM from 2013 (Upper Hazeltine Creek only); and
- A post-event DEM created from LiDAR from August 5, 2014.

The dates, data type, scale / resolution and source of each DEM are presented in Table 3-3.

Table 3-3: Metadata for digital elevation models

Pre- or Post-event	Data Type	Date	Resolution / Scale	Compiled By
Pre-event	Photogrammetry	27 September 2013	1:57,000	Eagle Mapping Ltd.
Pre-event	Terrain Resource Information Management (TRIM)	093A.042 and 093A.052: 2006-07 093A.043 and 093A.053: 1999-00	1:20,000	BC Ministry of Environment, Lands and Parks
Post-event	LiDAR	5 August 2014	0.25m	McElhanney Consulting Services Ltd.

Unfortunately, each DEM was generated at a different time and using a different technique, making accurate and systematic comparisons between pre- and post-event DEMs impractical. Elevations were different between the TRIM, 2013 and 2014 (LiDAR) DEMs and differences were non-systematic outside of the area affected by the TSF dam failure. Previous DEMs were coarser than the LiDAR surface and the 2013 DEM was restricted to the upper portion of Hazeltine Creek. Ultimately, LiDAR data collected post-event was chosen for analysis because of the substantial detail and event-relevant information it provided. The 2014 LiDAR DEM was used to create 1 m contours, hillshades and slope maps for interpretation and analysis.

3.1.4 Field geomorphic assessment

The post-event geomorphology of Hazeltine and Edney Creeks was assessed in the field using procedures modified from those outlined in the BC guidelines for channel assessment procedure (Ministry of Forests, 1996) and incorporated into SNC-Lavalin's specialized fluvial geomorphology assessment procedure. A field program was conducted from September 22-28, 2014. The objectives of the field program were to:

- Document the geomorphology of Hazeltine and Edney Creeks following the TSF dam failure and subsequent debris flow;
- Measure the location, thickness and characteristics of tailings and reworked sediments on the floodplain and channel;
- Characterize the impacts on the channel and floodplain (i.e., sedimentation, bank erosion, changes in morphology, slope and cross-sectional changes and debris flow); and.
- Identify areas of active erosion and sedimentation.

72 soil pits and exposures within 23 reaches along the Hazeltine Creek were characterized. The following data was recorded (Figure 3-1):

- Site station and UTM coordinates (NAD 1983, zone 10);
- Main-channel characteristics (channel form and field morphology, sediment patterns and channel and bank stability) recorded on SNC-Lavalin's specialized channel assessment field cards;
- Cross-sectional sketches;
- Site photographs;
- Field indicators for stream disturbance (Ministry of Forests, 1996); and,
- Flood heights where appropriate.

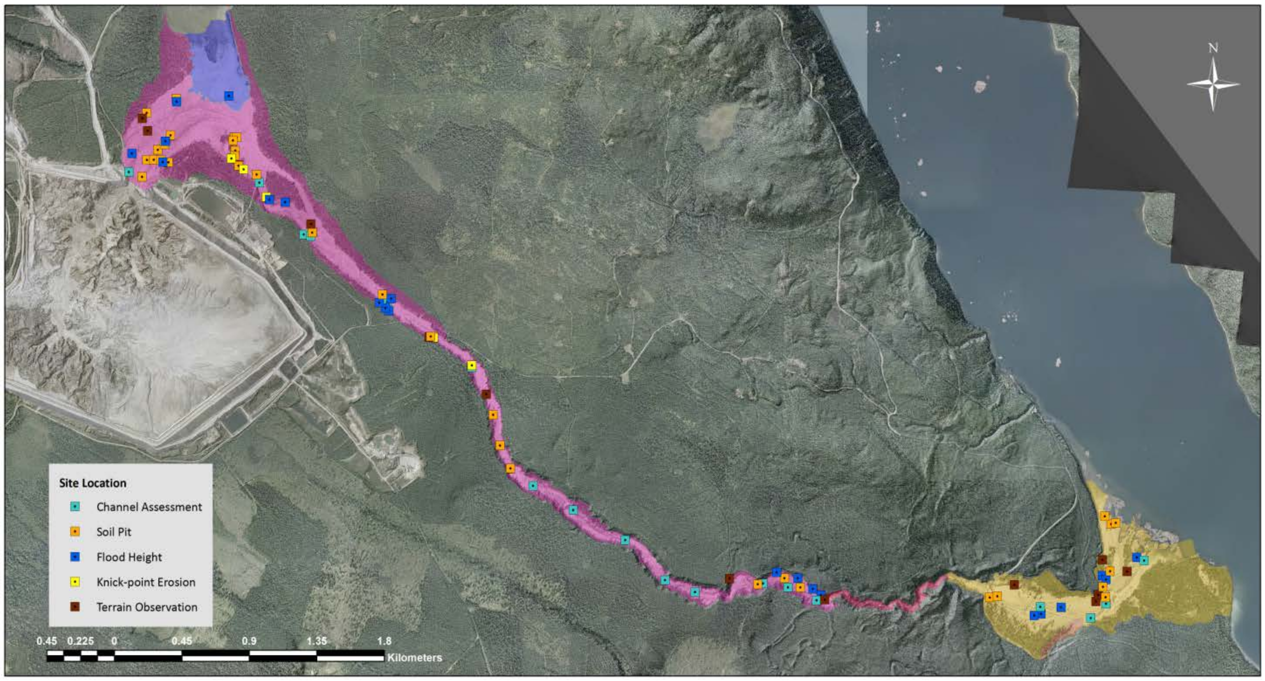

Figure 3-1: Geomorphology assessment site investigation locations

3.1.5 Video and air reconnaissance

The Cariboo Regional District shot video (Cariboo video) from a helicopter on the morning of August 4, 2014, about 8 hours after the TSF dam failure, but while it was still in progress (Morgenstern *et. al.*, 2015). This video was reviewed to inform the geomorphology assessment of Hazeltine Creek.

Three reconnaissance flights were conducted by helicopter on August 29, September 5 and September 22, 2014 by Leif Burge, Vanessa Cuervo, Richard Guthrie and Jeremy Zandbergen with the purpose of identifying:

- Active geomorphologic processes in the Hazeltine Creek channel (areas of active erosion and deposition);
- Hazeltine Creek geomorphology and bank stability;
- Critical areas for ground inspection; and,
- Accessibility and safety conditions for ground inspection.

Photographs were taken during all flights.

3.1.6 Delineation of the area affected by the event

The extent of area affected by the event was manually digitized on-screen using ESRI® ArcMap™ at a scale of 1:1,000. The terrestrial affected area was delineated based on a hillshade model, slope model, 1 m contours derived from the 2014 LiDAR, post-event orthophoto and field data (soil pits, photographs and field notes). Topographic data derived from the 2014 LiDAR data were created using the Spatial Analyst extension of ESRI® ArcMap™ software.

The following criteria were used to delineate the terrestrial affected area boundaries:

- Field evidence (from soil pits and photographs) indicating either erosion or deposition of material from the event; and,
- Observable evidence on the post-event orthophotographs indicating geomorphological impacts from the event (e.g., removal of vegetation, disturbed ground, eroded bedrock, debris jams or wood and boulders with some logs splintered, shattered or broken, etc.).

When visual confirmation was not possible, the delineation of the terrestrial affected area boundary was based on morphological features (slope and elevation contours).

Two different areas were defined:

- Terrestrial affected area: zones of erosion and/or deposition, including Large Woody Debris (LWD).
- Displaced material: material removed from its original position by erosion processes. Includes areas absent from the distal zone of the pre-event Hazeltine Creek delta surface.

The total impacted area includes both the terrestrial affected area and displaced material. Uncertainty in the delineation of the terrestrial affected area was due to dense forest cover that obscured the affected area boundary. In these locations, topography was used to interpolate between areas where the boundary of the terrestrial affected area was easily identified on the orthophotographs or from soil data.

3.1.7 Post-event distribution of surficial materials

Soil data and field mapping of the post-event Hazeltine Creek bed and floodplain displays evidence of the deposition of tailings and reworked native material. Material deposited within the channel and on the floodplain of Hazeltine Creek is composed of fine tailings, coarse tailings, native material, LWD, and a mixture of tailings, native material and LWD. Native material includes glacial till, lacustrine silts and glacial sands.

Understanding the location and extent of surficial materials and interaction between active geomorphic processes (during and following the event) and the surface material, provides insight into the Hazeltine Creek channel and floodplain evolution following the August 2014 event.

This analysis provides:

- The location and extent of surficial material (tailings and native materials);
- Identification of active geomorphic processes on the channel and floodplain;
- An estimate of the volume of tailings deposited within the terrestrial affected area. Volume deposition in Polley and Quesnel Lakes and volume balance are presented in Tetra Tech EBA Inc. (2015) report.

The surficial material was mapped within the terrestrial affected area. The map classifies areas (polygons) with defined material type (tailings and native soil), surficial landforms and geomorphic processes. A terrain unit symbol was assigned to each identified polygon based on the British Columbia terrain classification scheme (Howes and Kenk, 1997). The classification was modified to include processes related to this particular event. The following information was recorded during the mapping:

- Surficial material type (tailings and native soil);
- Texture where appropriate;
- Surface expression; and,
- Geomorphological processes (e.g., knickpoint erosion, slope failures, and avulsion).

An example of the terrain coding is presented in Figure 3-2.Terrain unit polygons were manually digitized on-screen using ESRI® ArcMap™ at a scale of 1:1,000. Topographic data described in Section 3.1.6 were used as baseline information to delineate terrain polygons.

Surficial material and tailings extent data were obtained from post-event field programs conducted during Fall 2014 and Winter 2015. Field data on the thickness of deposited material were compiled from different site investigation programs (Table 3-4) and georeferenced for analysis. In total, 229 locations were used in the surficial material-tailings extent mapping and deposition analysis.

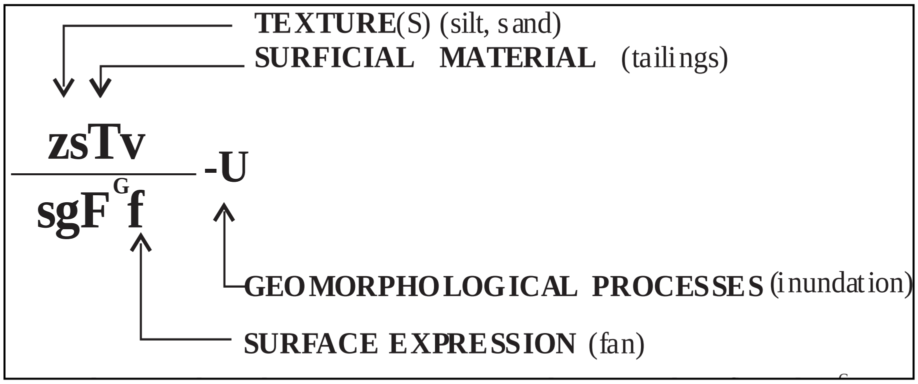

Figure 3-2: Example terrain unit symbol that describes a silty-sandy (zs) Tailings (T) veneer (v) overlaying a glaciofluvial (FG) fan (f) composed of sandy gravel (sg) modified by inundation (U)

All site locations included in the analysis contain UTM coordinates and depth of tailings and texture (where appropriate). Locations of thickness measurements were well distributed in areas of greatest deposition, including upper Hazeltine Creek adjacent to the TSF, the Plug area and Lower Hazeltine Creek.

Table 3-4: Site investigation soil pit locations used in surficial mapping and deposition analysis

Source of data	Number of soil locations	Remediation Area	Data collection method	Reference
Hydrology – Geomorphology Impact Assessment (HIA)	72	PP, UHC, CHC, LHC, LEC	Soil pit	Hydrotechnical and geomorphological Impact Assessment, 2015 (Appendix 1, Post-Event Environmental Assessment Report)
Soil Quality Impact Assessment (SIA)	89	PP, UHC, CHC, LHC, LEC	Soil pit	SNC-Lavalin Inc.(2015) (Appendix 4, Post-Event Environmental Assessment Report)
Panel Investigation Report (PIR)	23	UHC	Drill hole	Independent Expert Engineering Investigation and Review Panel (2015)
Mount Polley Investigation (MPI)	45	PP, UHC	Excavator	Eagle Crest Silviculture (Field data from February, 2015)
Archeology Impact Assessment (SIA)	317	LHC	Soil pit, trenches	ARCHER Field data

Note: Polley Plug (PP); Upper Hazeltine Creek (UHC); Canyon Hazeltine Creek (CHC); Lower Edney Creek (LEC); Lower Hazeltine Creek (LHC).

3.1.8 Volume of deposited material

The pre-event DEMs were insufficient for direct comparison against post-event topography to determine the volume of deposits within Hazeltine Creek. Volumes of materials deposited on channel and floodplain were therefore estimated based on field data collected on the thickness of deposited material (Table 3-4), mapping of surficial material within the channel and floodplain (Appendix E), and photographs taken in the field.

Terrain polygons derived from the surficial material mapping were used to interpolate tailings thickness. When tailings thickness data were not available for a terrain polygon, the closest thickness value in similar terrain was used. The following thickness intervals were defined and assigned to terrain polygons (less than or equal 0.1 m, 0.11-0.19 m, 0.20-0.49 m, 0.5-0.99 m, 1.0-1.49 m, 1.50-1.99 m, 2.0-2.49 m, 2.50-2.99 m, 3.00-3.49 m and greater than or equal 3.5 m). Volume of deposition was estimated by multiplying average deposition thickness in the polygon by the area of the terrain polygon.

The thickness of deposits along Hazeltine Creek is spatially heterogeneous. No estimation method is likely to provide 100% accuracy in the estimation of deposition volumes. Limitations and sources of uncertainties to this analysis are:

- The delineation of the terrestrial affected area is based on the interpretation of the post-event orthophoto and LiDAR. Limited field data exist outside the identified terrestrial affected area and ground truthing of this area has not been conducted. Potential errors in the delineation of the terrestrial affected area boundaries could lead to errors in the estimation; and,
- Soil field data are not systematically distributed within the study area and terrain polygons. Furthermore, few soil pit locations are available within the canyon section making the estimation less reliable. This may result in over or under estimation of deposition volumes.

Limitations related to collection of soil field data in the different site investigation programs are outlined in their respective reports.

3.1.9 Post-event estimation of net erosion

Overall, the post-event Hazeltine Creek bed shows evidence of net erosion. Evidence for erosion includes the lack of vegetation, lack of well developed soil, exposure of native glacial material within the erosion zone and large knickpoints. Digital pre-event data (2013 and TRIM DEMs) are not of sufficient accuracy for direct comparison between pre- and post-event topography to determine the net volume or depth of erosion which occurred during the event.

Net volume and depth of erosion were estimated based on the determination of pre-event floodplain elevations using morphological, sedimentological and photographic evidence. 96 cross-sections were extracted from the post-event LiDAR-derived DEM. Each cross-section was georeferenced in GIS for analysis. The location of the pre-event floodplain was determined from the:

- Remnant floodplain levels seen in the post-event LiDAR;
- Shape of the adjacent valley sides, used to estimate the floodplain levels where appropriate;
- Downstream profile of the estimated elevation of the floodplain, used to corroborate the floodplain levels at each cross-section; and,
- Post-event orthophotographs, field photographs and oblique aerial photographs taken from helicopter, used to aid in the interpretation of the remnant floodplain locations. In some areas in situ roots indicate the location of former floodplain.

A floodplain elevation was estimated for the right and left bank by identifying terrace levels. Cross-sections were compared upstream and downstream for consistency. The floodplain level was represented for each cross-section as a horizontal line from the average of the right and left bank elevations. Often cross-sections show several terrace levels. The analysis was conducted separately by two specialists with training and experience in river geomorphology. At each cross-section, the lowest and highest terrace levels that represent the likely floodplain elevation were estimated for each bank. This provided a minimum and maximum estimate for the volume eroded from the valley and quantified the level of uncertainty in the estimate. A large difference in the floodplain elevation between interpreters at any particular cross-section represents lower confidence in the identification. The maximum and minimum erosion volumes were mapped to show areas of lower and higher confidence in the estimates.

To estimate the net erosion depths, elevations of stations on each cross-section elevations were subtracted from the estimation for the minimum and maximum elevation of the former floodplain at each cross-section. The average of these depths provided an estimate of net erosion depth for each cross-section.

To estimate the net volume of erosion, the mean net erosion depth was multiplied by the area of erosion represented for each cross-section. The width of erosion for each cross-section was calculated based on linear difference between points where average elevation of the estimated floodplain level encountered the ground surface. The length of channel segment at each cross-section was calculated based on length between the point halfway between each cross-section and the next upstream cross-section and the point halfway between the cross-section and the next downstream cross-section.

The volume represented by the typical pre-event channel cross-section as defined in Minnow (2007) was subtracted from the estimated erosion volume for each post-event cross-section for the length of the stream.

Limitations and sources of uncertainty:

- The pre-event floodplain is represented by a horizontal line; however floodplains are not strictly horizontal and have topographic differences across a section. These topographic differences are unknown because they were erased by the event and the pre-event data is unreliable (See Section 3.1.3);
- The erosion of soil and vegetation on the floodplain is not accounted for in this analysis;
- Higher terraces identified as floodplain may be relic and may not represent the true pre-event floodplain level; and,
- Lower terraces identified as the floodplain may have formed during or following the TSF dam failure and may not represent of the true pre-event floodplain level.

3.1.10 Assessment of slope and bank stability

The post-event banks and valley walls of Hazeltine Creek display evidence of slope failures. Stability of valley slopes was determined using a ranking system based on the combination of input factors that are considered important for slope stability in the area (slope class, surficial material and active processes). Expert knowledge was used to weight these factors (Table 3-5). Weights for each factor were added up and final scores were grouped into five categories ranging from Class I (no significant slope stabilities) to Class V (highly unstable terrain).

Slope stability was mapped based on the following data:

- Slope angles derived from LiDAR;
- Mean annual flow levels; and,
- Post-event orthophotograph, ground truthing, field photographs, and oblique aerial photographs taken from a helicopter.

Table 3-5: Weight values to define valley wall slope stability classes

Weight Value	Dominant Slope Class	Surficial Material	Active Processes
1	Very gentle slope (0-3°)	Bedrock (R)	Gully and rill erosion (-V) and slope failures runout areas (-R)
2	Gentle slope (3.1-15°)	Till (M)	Slope failure initiation areas (-R")
3	Moderate slope (15.1-26°)	Glaciofluvial (F^G), Fluvial (F), Colluvial (C),	-
4	Moderately steep slope (26.1-35°)	Glaciolacustrine (L^G), Fluvial (F), and tailings (T)	-
5	Steep slope (> 35°)	-	-

The stability of the channel banks of Hazeltine and Lower Edney Creek was calculated using a modified version of the Bank Erosion Stability Index procedure, or Bank Erosion Hazard Index (BEHI) developed by Rosgen (1996; 2001). This methodology utilizes a rank system based on channel banks characteristics that contribute to bank stability. Channel bank criteria used to determine BEHI is presented in Table 3-6. Channel bank stability was mapped based on the following data:

- Depths of flow for the mean annual flow obtained from River2D model (model and data described in Section 5.3.1.11) results.
- Ground surface elevations along channel cross-sections collected from 2014 LiDAR data;
- Bank slope angles calculated as the ratio of the bank height to the horizontal distance between the bank top and bank toe; and,
- Surficial material map.

BEHI values were calculated for both the left and right banks of cross-sections spaced at approximately 100 m intervals along Hazeltine Creek and the lower reach of Edney Creek. The bank height-depth ratio was calculated using the vertical distance from the top to the toe of the bank and the mean annual flow depth. Elevations of the ground surface along channel cross-sections were collected from 2014 LiDAR data. Bank angles were calculated from the bank height and the horizontal distance between the bank top and the bank toe. The bank material adjustment value was determined from surficial material deposits observed in the field.

The present channel banks lack vegetation or surface protection, resulting in assignment of the maximum BEHI value for these variables for each cross-section bank. Maximum BEHI values for bank stratification were also assigned to all banks. Root density, surface protection and root depth to bank height ratio values were zero and therefore were excluded from the calculations to provide meaningful results. Rating scale was adjusted to reflect normalized values allowing for differences in relative bank stability along the channel. An empirical function was applied to each variable to obtain BEHI ratings for each variable. Ratings were then summed to give the total BEHI score. The score was categorized from very low to very high to describe relative stability of the banks at each cross-section.

Table 3-6: Criteria to define bank erosion hazard index (modified from Rosgen, 2001)

Bank Erosion Potential	Slope Angle (degrees)	Bank Height Ratio[1]	Bank Surface Protection (%)[(2)]	Totals
I (Very Low)	–less than 2°	Stable (>1.1)	80-100	2 - 3.9
II (Low)	2 – 3.9°	slightly incised (1.1-1.19)	55-79	4 - 7.9
III (Moderate)	4.0-5.9°	moderately incised (1.2-1.5)	30-54	8 - 11.9
IV (High)	6.0-7.9°	Incised (1.6-2.0)	15-29	12 – 15.9
V (Very High)	greater than or equal 8°	deeply incised (>2.1)	< 15	Greater than 16

Notes: 1. The ratio of bank height to depth of flow under bankfull conditions.
2. Present channel banks lack vegetation or surface protection. Maximum score was used for these variables. Adjustment for nature of bank materials and stratification: (i) Bank Materials: Bedrock (very low), Boulders (low), cobble (subtract 10 points unless gravel/sand greater than 50%, then no adjustment), gravel (add 5-10 points depending on % sand), sand (add 10 points), silt/clay (no adjustment). (ii) Stratification: Add 5-10 points depending on the number and position of layers.

3.1.11 Post-event hydraulic patterns

A hydraulic model was developed to identify areas susceptible to erosion and deposition following the event. The model was developed to predict patterns of inundation extent, depth and velocity and shear stress for the MAF, 10-year and 100-year return intervals.

3.1.11.1 Modeling Approach

The hydraulic modeling of Hazeltine Creek was completed with the two-dimensional hydrodynamic model River2D developed in the University of Alberta by Steffler and Blackburn (2002). River2D has been applied in numerous studies of natural streams and rivers to compute 2D flow distribution and habitat characterization. The model has the capabilities of computing subcritical and supercritical flows, and wetting and drying up of channel bed, which are important features for natural channels with varying inflows. This model was selected for studying general two-dimensional mean flow pattern for selected flows in Hazeltine Creek due to our previous successful experiences with this model in application to small creeks.

The total length of the Hazeltine Creek modeling study reach was 7.9 km. A short reach of Edney Creek (0.7 km long) was included in the study area to model Hazeltine Creek-Edney Creek confluence and the downstream reach. The upstream boundary was set near the TSF, and the modeling domain extended 0.6 km beyond the confluence of Hazeltine and Edney Creeks, approaching Quesnel Lake. The study area was divided into four reaches considering channel characteristics, topography and flows. To provide 2D model design flow boundary conditions Hazeltine Creek was modeled initially with the one-dimensional HEC-RAS model (USACE, 2010).

3.1.11.2 2D Model Parameters

Model parameters for 2D modeling were selected based on characteristics of individual reaches. River2D is a two-dimensional, depth averaged hydrodynamic and fish habitat model developed based on Finite Element formulation. The model generally runs in unsteady flow mode which can be used to obtain a steady state solution. The details of the model theory are available in the Steffler and Blackburn (2002).

The hydrodynamic component of the River2D model solves the two-dimensional, depth averaged St. Venant Equations expressed in conservative form. Three equations representing the conservation of water mass, and momentum vectors in two directions (x and y) are solved with appropriate boundary and initial conditions. Triangular mesh elements with a linear distribution of variables between the nodes are used. The dependent variables for solutions are the depth and discharge intensities in the two respective coordinate directions.

Friction slope terms in the depth averaged momentum equations are related to the bed shear stress, which are dependent on the depth average velocity vector, depth of flow and bed roughness. The effective roughness height (k_s) is one of the important parameters for natural channel bed boundary. The Boussinesq type eddy viscosity formulation is used in the model for computing depth averaged turbulent shear stresses with the eddy viscosity coefficient (η_t) as a multiplier of velocity gradients. The eddy viscosity coefficient is composed of three terms: a constant, bed shear generated term, and the transverse shear generated term. The parameters related with eddy viscosity are important for model calibration. River2D handles wetting-drying phenomena by using groundwater flow equations assuming an artificial aquifer in those areas which provide a continuous stable solution in both wet and dry areas. The drying up threshold depth, transmissivity and storativity are another three parameters which are adjusted during model calibration based on the site conditions.

3.1.11.3 Data Preparation

Data and information used in the model development were:

- High resolution LiDAR topography data acquired on August 5, 2014. This provided model bathymetry. The horizontal and vertical accuracy of the data was 5 cm or better. No further channel bathymetric measurements were conducted;
- Regional flow analysis. This provided discharges for Mean Annual Flood, and 10-year and 100-year return period floods for different reaches of Hazeltine and Edney Creeks; and,
- Post-event satellite imagery and photographs from site reconnaissance following the August 2014 TSF dam failure. This provided a guide to determine the physical status of the channel.

GIS software was used initially to process DEM data and to develop a HEC-GeoRAS model to determine water level elevations at different sections of the creek with HEC-RAS. It is noted that LiDAR data were collected shortly after the TSF dam failure. Thus, the channel bathymetry created from the LiDAR data does not provide a truthful representation of the channel bed due to pooled water and liquid tailings in the relatively low areas of the creek. Also, the captured LiDAR bathymetry does not represent a fully water-worked channel as no large flood flow occurred between the original TSF dam failure debris flow and the LiDAR data acquisition. Current bathymetry condition in some sections of the creek is likely to be different than the LiDAR surface.

3.1.11.4 Model Setup Procedures

The model for the study area was developed by creating bathymetry for the reaches. The physical model boundaries and model reach lengths for numerical space discretization were determined based on anticipated flow conditions at the boundaries and the size of the computational mesh. Preliminary numerical simulations were conducted for defining the final domain boundaries in each river reach. Table 3-7 and and Table 3-8 present the extent of model reaches, and boundary conditions used for model setup. Four separate models were created for the reaches, introduced below.

- Upstream Reach Model: The upstream reach model inflow boundary was located at the Hazeltine Creek section closest to the TSF dam failure site. The total channel length was 2.7 km which extended 1.2 km downstream of the Gavin Bridge Road crossing. The average slope of the channel was 0.71%, varying from 0.7 to 1.2%. Several steep sections and/or knickpoints of the channel bed were located in this reach.
- Middle Reach Model: The length of this reach was 1.45 km. This model reach consisted of local steep sections, and multiple narrow channels. One section of creek upstream of the largest knickpoint was too tall for hydraulic modeling using River 2D because the model results cannot be converged. This section was therefore excluded from analysis.
- Downstream Reach Model: The upstream boundary of this model reach overlapped with the middle reach model and extended up to the Horsefly-Likely Forest Service Road (FSR) (Ditch Road) crossing. The 2.4 km long reach was characterized by bifurcated channels and the steep narrow canyon.
- Confluence Area and Delta Reach Model: To model the Hazeltine and Edney Creek confluence and the downstream area to Quesnel Lake, a 0.7 km reach of the Edney Creek was included in the model. Edney Creek flows are in the order of double the flows of Hazeltine Creek (Table 3-8).

The accuracy of the model also depends upon the mesh resolution for a given computational algorithm (Steffler and Blackburn, 2002). For Hazeltine Creek modeling, initially a model response analysis approach was employed to determine an appropriate mesh resolution. Results of initial simulations were analysed by comparing water surface elevations, velocity distribution and overall model convergence and stability. The mesh was modified and refined until there was no significant variation in computed flows and a logical flow pattern was computed through narrow channels and drops. The final mesh was composed of triangular elements with a spatial resolution of nodes ranging from 0.25 m to 1 m in the wetted areas and up to 4 m in dry areas. Figure 3-3 shows a typical model section of mesh and bathymetry.

Field observations and LiDAR data indicated that the main channel and lower floodplain were composed of predominantly finer materials and vegetation was absent on the floodplain. In many sections the main channel was poorly defined as it had not yet been reworked under high flows following the TSF dam failure.

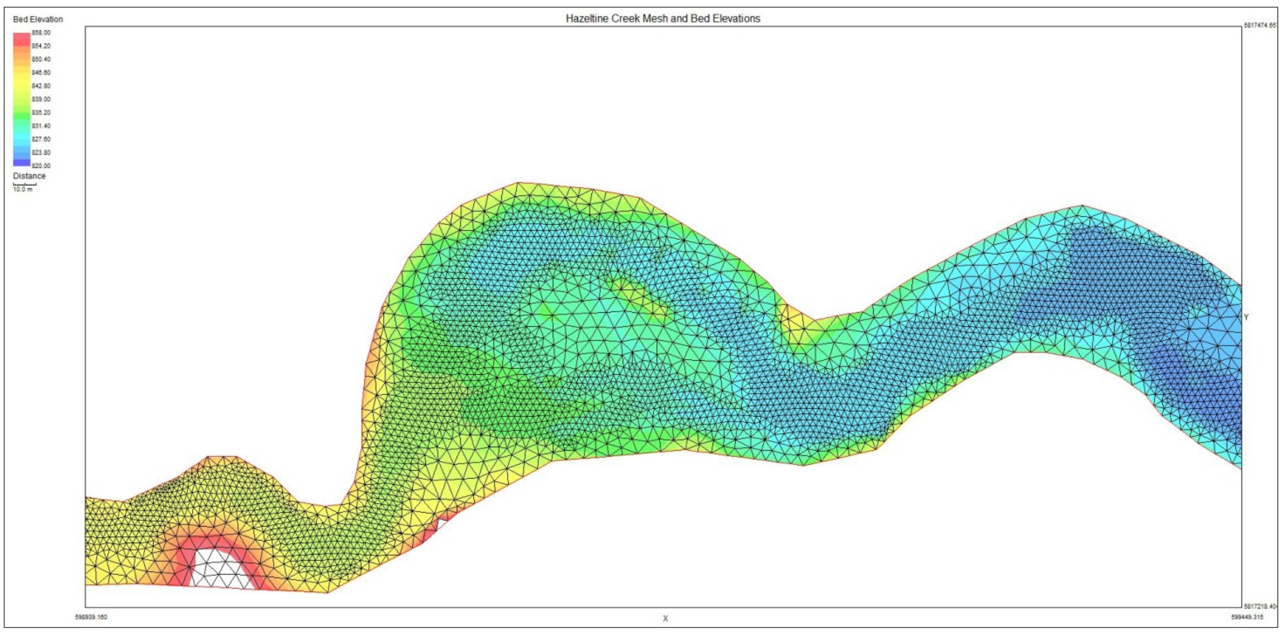

Figure 3-3: Typical meshing and bathymetry used in the model (selected from Downstream Reach Model)

Parameterizations of the model consisted of the selection of appropriate bed resistance, eddy viscosity coefficients, wetting-drying parameters and time step (Steffler and Blackburn, 2002). Eddy viscosity represents the loss of energy due to creation of eddies in turbulent flow. Bed resistance is important for stream flow modelling because the prediction of flow (velocity and bed shear) using the shallow water equations is largely dependent on the friction parameter values adopted in the model. Following trial model runs and examination of model response, parameter values were selected based on reach characteristics and modeler experience. Calibration of the model was not performed in this study as observed data (water level and velocity) were not available but a cross-comparison of results was conducted with mean velocities obtained from simplified calculations.

Table 3-7: Hazeltine Creek 2D model reaches

Reach Name	Upstream Boundary Easting (m)	Downstream Boundary Easting (m)	Total Length of Channel (km)
Upstream Reach	597599	597600	2.70
Middle Reach	697666	598856	1.45
Downstream Reach	598645	600731	2.40
Confluence and Delta Reach	600685	601814	2.00

Table 3-8: Hazeltine Creek model boundary conditions

Model	Model Run ID	Flow Return Period	Inflow (m^3/s)	Downstream Boundary Water Level Elevation (masl)
Upstream Reach	HCUSQ100	Mean Annual Flood	1.6	879.84
	HCUSQ10	10 Year	2.5	879.89
	HCUSQ2	100 Year	3.7	879.94
Middle Reach	HCMQ100	Mean Annual Flood	1.8	845.06
	HCMSQ10	10 Year	2.8	845.10
	HCMSQ2	100 Year	3.7	845.15
Downstream Reach	HCDSQ100	Mean Annual Flood	1.8	746.51

	HCDSQ2	100 Year	3.7	746.56
Confluence and Delta Reach	LEC-HCQ100	Mean Annual Flood	1.8 (Hazeltine Cr), 4 (Edney Cr)	726.42
	LEC-HCQ10	10 Year	2.8 (Hazeltine Cr), 6.2 (Edney Cr)	726.32
	LEC-HCQ2	100 Year	3.7 (Hazeltine Cr), 9.2 (Edney Cr)	726.23

4 PRE-EVENT CHANNEL AND FLOODPLAIN GEOMORPHOLOGY

Prior to the TSF dam failure, Hazeltine Creek flowed through a well-defined, generally single unconfined channel within a largely alluvial valley incised into the Fraser Plateau from Polley Lake to Quesnel Lake (Minnow, 2012). The slope of the Hazeltine Creek channel increased downstream after leaving Polley Lake, flowing through a wetland and reaching a maximum within the Hazeltine Creek Canyon (Triton Environmental Consultants Ltd., 1991)(Triton Environmental Consultants Ltd. , 1991). Downstream of the Canyon the slope decreased as the channel flowed into the Hazeltine Creek Delta located at the creek interface with Quesnel Lake (Minnow, 2007). Minnow (2007) records the geomorphology of eight (8) reaches in Hazeltine creek. Data from this report are used extensively to document the geomorphology of the pre-event channel and floodplain geomorphology of Hazeltine Creek.

Historical anthropogenic activities including water diversion, livestock grazing, mining and logging within the Hazeltine Creek watershed have affected the geomorphic characteristics of Hazeltine Creek (IMC, 1990; DFO, 1990; Rood and Hamilton, 1995; Rowland and MacDonald, 1996 and Nener and Wernick, 2000). In 1991 the Hazeltine watershed was 53% forested, 26% recent harvest, 9% green-up (logged greater than 30 years prior) and 12% lake (Triton Environmental Consultants Ltd., 1991). However, logging efforts in the watershed have been scaled back over the last decade and decrease in forest cover is now primarily associated with mining activities (Knight Piesold, 2014; Rowland and MacDonald, 1996). Early diversion of Hazeltine Creek (c. 1913) associated with placer mining was remediated following World War II and flow to the original channel restored (Knight Piesold, 2009; Imperial Metals Corporation, 1990. Given the time frame, it is likely that the geomorphic regime of Hazeltine Creek had reached equilibrium following the altered discharge regime.

Time series analysis was conducted using aerial photographs from 1974, 1996 and 2009. Analysis shows that overall channel planform has remained relatively stable over time. Changes observed between historical aerial photographs occurred in areas of low slope where beaver (*Castor canadensis*) dams have been reported (Imperial Metals Corporation, 1990; Pedersen, 1998; Minnow, 2007). The presence of beaver dams is a control on the channel's geomorphology. The presence of a dam impounds water and sediment upstream and generally alters downstream velocity and discharge of water and sediment. However, high flow conditions can lead to the formation of spillways and, over time, these spillways may become permanent channels, shifting the overall planform of the stream (Gurnell, 1998).

Depositional areas observed along Hazeltine Creek were mostly thin accumulations in backwaters and small shallow pools, likely depositing and eroding seasonally (Minnow, 2012). Channel width, depth and bed material were highly variable due to woody debris in the channel (Knight Piesold Consulting, 2009b). The creek was characterized by dense riparian vegetation (Minnow, 2007) (Figure 4-1).

Five areas, defined in the report introduction, will be used to describe the pre-event channel and floodplain condition: the Plug area, Upper Hazeltine Creek, Hazeltine Creek Canyon, Lower Hazeltine Creek and Edney Creek.

Figure 4-1: (A): Second reach of Lower Hazeltine Creek (HC-R8) flowing through cedar lowland habitat. (B) First reach of Upper Hazeltine Creek (HC-R1) showing densely vegetated riparian zone (January 20, 2007)

4.1 Plug Area

The “Plug area” of Hazeltine Creek extends from the creek’s outlet at Polley Lake to 1,750 m downstream. Prior to the TSF dam failure, the Plug area was characterized by a wide, low sloping wetland region (Minnow, 2007). Channel sinuosity in this area was 1.1 as measured from 2009 aerial photographs. Time series analysis showed historically within this section, and extending into Upper Hazeltine Creek, the creek split into two main channels with a network of minor interconnecting channels and ponds. However, by 2009 only a single well-defined channel remained. In some channel sections, flow was controlled by beaver activity (e.g., USW7 Pond, Minnow, 2007). No detailed pre-event field data have been found for this area.

The confluence of Bootjack Creek and Hazeltine Creek was within the Plug area, 770 m downstream from the Polley Lake outlet. Contribution of discharge from Bootjack Creek was limited by the diversion of Bootjack Lake flow circa 1913 (Pederson, 1998). Diversion reduced the watershed area of Bootjack Creek above its confluence with Hazeltine Creek by 70% (to approximately 4.2 km^2) (Knight Piésold Consulting, 2009a). MPMC has further reduced the watershed area through water management.

4.2 Upper Hazeltine Creek

Upper Hazeltine Creek begins 1,750 m downstream of the Polley Lake outlet and extends to the upstream end of the Hazeltine Creek Canyon, 5,897 m downstream. Channel sinuosity in this area was 1.2 as measured from 2009 aerial photographs. Time series analysis reveals channel shifting over time near the upper boundary of this section. However, this section is more typically defined by a stable channel, with greater stability in its downstream reaches. Channel aggradation in Upper Hazeltine Creek appears to fluctuate throughout time. This area coincides with reaches one (1) to five (5) as described by Minnow Environmental Inc. (2007). Time series analysis reveals no observable change in channel position within Upper Hazeltine Creek.

This section of channel displays several morphologies divided into five (5) distinct reaches defined in (Minnow, 2007).

The first uppermost reach of Hazeltine Creek (HC-R1), was 445 m in length, displayed a riffle-pool morphology characterized by a low gradient (1.4%), and bankfull depth and width of 0.36 m and 7.0 m, respectively (Pedersen, 1998; Minnow, 2007). Banks were generally stable, composed of fine-grained material and stabilized by the presence of dense vegetation (Minnow, 2007).

The second reach (HC-R2), a 210 m section downstream of the first reach, was characterized by ponded flow resulting from a downstream beaver dam (W7 Pond, Minnow Environmental Ltd., 2007). The length of ponded channel was 210 m and ponding typically occupied the entire floodplain at 45 m wide and 100 cm deep (Minnow, 2007).

Downstream of the beaver dam, the third reach (HC-R3) was 157 m in length, ending at the Gavin Lake Road. This riffle-pool reach was low gradient (0.8%) with a bankfull width and depth of 7.9 m and 0.12 m, respectively. It was characterized by the presence of side-channels and unstable banks (Minnow, 2007). The presence of beaver ponds likely exerted control over local patterns of deposition and erosion in Upper Hazeltine Creek. Beaver dams create retention ponds which slow velocity and trap sediment, causing overall aggradation of the channel bed. Downstream of the dam, sediment starvation can lead to erosion of the channel bed and banks, which over time can result in bed degradation or lateral channel migration (Gurnell, 1998). This may have contributed to the low bank stability reported by Minnow (2007).

Downstream of Gavin Lake Road, within reach four (HC-R4), the channel became more confined as gradient steepened (1.7%), channel width narrowed (4.7 m) and bed material coarsened in the next 2,200 m downstream (Minnow, 2007). Surface water flow was variable and hyporheic flow (mixing of shallow groundwater and surface water) was suspected. Bank stability was low within the reach, with some areas of undercutting (Minnow, 2007) (Figure 4-2).

Figure 4-2: Undercut banks in reach four of Hazeltine Creek. Photo from Minnow (January 20, 2007)

The downstream most fifth reach (HC-R5) in Upper Hazeltine Creek displayed riffle-pool morphology. Channel gradient (3.7%) and confinement continued to increase, producing corresponding changes in bankfull width (4.5 m) and depth (0.38 m) (Minnow, 2007). Banks were considered moderately stable and in two locations (Minnow, 2007) the valley walls had failed into the creek (Minnow, 2007) (Figure 4-3).

Figure 4-3: Bank failure in reach five of Hazeltine Creek. Photo from Minnow (January 20, 2007)

4.3 Hazeltine Creek Canyon

Hazeltine Creek entered a 1,510 m long canyon (HC-R6) 5,897 m downstream of the Polley Lake outlet. Channel sinuosity in this area was 1.1 as measured from 2009 aerial photographs. Time series analysis reveals this section of the creek is extremely stable showing no change over time. Both channel confinement and slope (7.3 %) were at a maximum through the canyon reach. Bankfull depth and width decreased to 0.27 m and 3.7 m, respectively (Minnow, 2007). The channel bed in this reach was lined with bedrock, boulders and cobbles, and displayed step-pool morphology. Steepening of channel gradient resulted in groundwater resurfacing and low flow discharges that were 25% higher than in the previous reach (Minnow, 2007). The Hazeltine Creek

Canyon included numerous debris jams and a 1.2 m cascade (Minnow, 2007). In some locations cobble had aggraded over log debris, resulting in sections of hyporheic flow (Minnow, 2007) (Figure 4-4).

Figure 4-4: Aggraded cobble over large woody debris within Hazeltine Creek Canyon producing sections of hyporheic flow. Photo from Minnow (January 20, 2007)

4.4 Lower Hazeltine Creek

Lower Hazeltine Creek includes the channel downstream of the Hazeltine Creek Canyon to the outlet at Quesnel Lake. Channel sinuosity in this area was 1.2 as measured from 2009 aerial photographs. Time series analysis reveals a widening channel and floodplain in this section. A large pool below the canyon exit and in the upper reaches of this section evident in 1974, disappeared by

1996. In addition, delta growth was recognized between 1974 and 1996. This section is defined by three (3) distinct reaches.

The first reach of Lower Hazeltine Creek (HC-R7) extended 350 m from the mouth of the canyon to just below Horsefly-Likely FSR (Ditch Road). This riffle-pool reach displayed a moderate gradient (2.7%) and a bankfull width and depth of 5.3 m and 0.37 m, respectively. Channel substrate was cobble with some areas of aggraded small cobbles. Banks were considered stable (Minnow, 2007).

The second reach (HC-R8) extended 555 m downstream of R7, from downstream of Horsefly-Likely FSR (Ditch road) to the confluence of Hazeltine and Edney Creeks. Slope decreased in the second reach (0.8%) and substrate decreased in grain size from cobble to gravel. The banks became less stable, comprised of a higher proportion of fines in the banks and bankfull width and depth decreased to 5 m and 0.27 m, respectively (Minnow, 2007).

The third and final reach (HC-R9) included the channel from the confluence of Edney and Hazeltine Creeks to the outlet at Quesnel Lake. Due to beaver activity Edney Creek contributed flow to Hazeltine Creek via two channels. The reach gradient increased to 1.0%, demonstrating riffle-pool morphology with small cobble and gravel substrates. Banks were considered to be relatively stable. Bankfull width and depth increased to 11.3 m and 0.43 m, respectively (Minnow, 2007).

4.5 Edney Creek

Prior to the TSF dam failure, the confluence of Edney and Hazeltine Creeks was located 850 m upstream of the outlet to Quesnel Lake[3]. Channel sinuosity in this area was 1.1 as measured from 2009 aerial photographs. Edney Creek contributed approximately 60% of the flow in Lower Hazeltine Creek (Minnow, 2007). Historically, the Edney Creek watershed was impacted by extensive logging practices. In 1991, 54% of the watershed was forested, 45% harvested and 1% was lake (Triton Environmental Consultants Ltd., 1991)(Triton Environmental Consultants Ltd. , 1991). In some cases, timber from the riparian area was harvested and cutblocks extended to the creek edge (Pedersen, 1998). There was potential for high impact from livestock grazing (Nener and Wernick, 2000).

The Edney Creek channel was considered relatively stable, with increasing gradient in its lower reaches (Triton Environmental Consultants Ltd., 1991)(Triton Environmental Consultants Ltd. , 1991). According to Triton Environmental Consultants Ltd. (1991) the stream appeared to be incised into the Fraser Plateau in the lower reach. Edney Creek was ponded by beaver dams upstream of the confluence of the creeks (Minnow, 2007) (Figure 4-5).

[3] Measured as distance along channel.

5 POST- EVENT CHANNEL AND FLOODPLAIN GEOMORPHOLOGY

On August 4th 2014, the TSF dam failure produced a complex response downstream. The resulting event travelled 9.4 km down through Hazeltine Creek, displaying both characteristics of a debris flood and debris flow. The estimated outflow volume was 25 Mm^3 (Imperial Metals, 2014; Table 5-1).

Field evidence indicates the event occurred as a sequence of surges characterized initially by discharge with high sediment concentrations typical of debris flows, followed by a decrease in discharge with low sediment concentrations typical of debris floods. In this report, the term debris flow is used to describe the rapid to extremely rapid surges of fine grain tailings, large woody debris and native material that travelled down Hazeltine Creek Channel following the TSF dam failure.

Table 5-1: Volume estimation for TSF dam failure.

Volume Estimation	Total
Supernatant water (Mm^3)	10.6
Tailings solids (Mm^3)	7.3
Interstitial water (Mm^3)	6.5
Construction materials (Mm^3)	0.6
Total outflow volume (Mm^3)	25.0
Net volume of eroded material (Mm^3)	0.6 To 1.7
Total volume of the event (Mm^3)[3]	25.6 To 26.7

The post-event geomorphology of Hazeltine and Edney Creeks is dominated by erosion of the pre-event channel and floodplain by materials released from and mobilized by the TSF dam failure, and the deposition of tailings, embankment material, and eroded native material. Flow from the event eroded Hazeltine Creek along its entire length, resulting in a wider and deeper channel. Sediments on the channel bed, native soil and forest located in and around the former Hazeltine Creek channel were removed from the valley floor.

Across the post-event surface, there is evidence for at least three different mechanisms of disturbance:

- Erosion, identified when native material remains present at the surface, indicating that erosion was the last process in these locations;

- Erosion followed by deposition identified when deposited material is present at the surface and the native vegetation is removed, indicating that the native material was eroded and deposition was the last process occurring in these locations. It is possible that cycles of erosion and fill occurred during the event and that evidence is absent due to subsequent erosion; and,
- Deposition identified by deposited material at the surface over native vegetation, indicating that the area experienced little or no erosion and deposition was the last process occurring.

5.1 Area Affected by the TSF Dam Failure

The release of tailings and water from the TSF produced direct impacts on the Hazeltine Creek channel and floodplain. The terrestrial area (including wetlands) affected by the dam failure and subsequent debris flow covers approximately 237.5 ha (Figure 5-1).

Figure 5-1: Pre- (A) and post-event (B) view of Hazeltine Creek channel

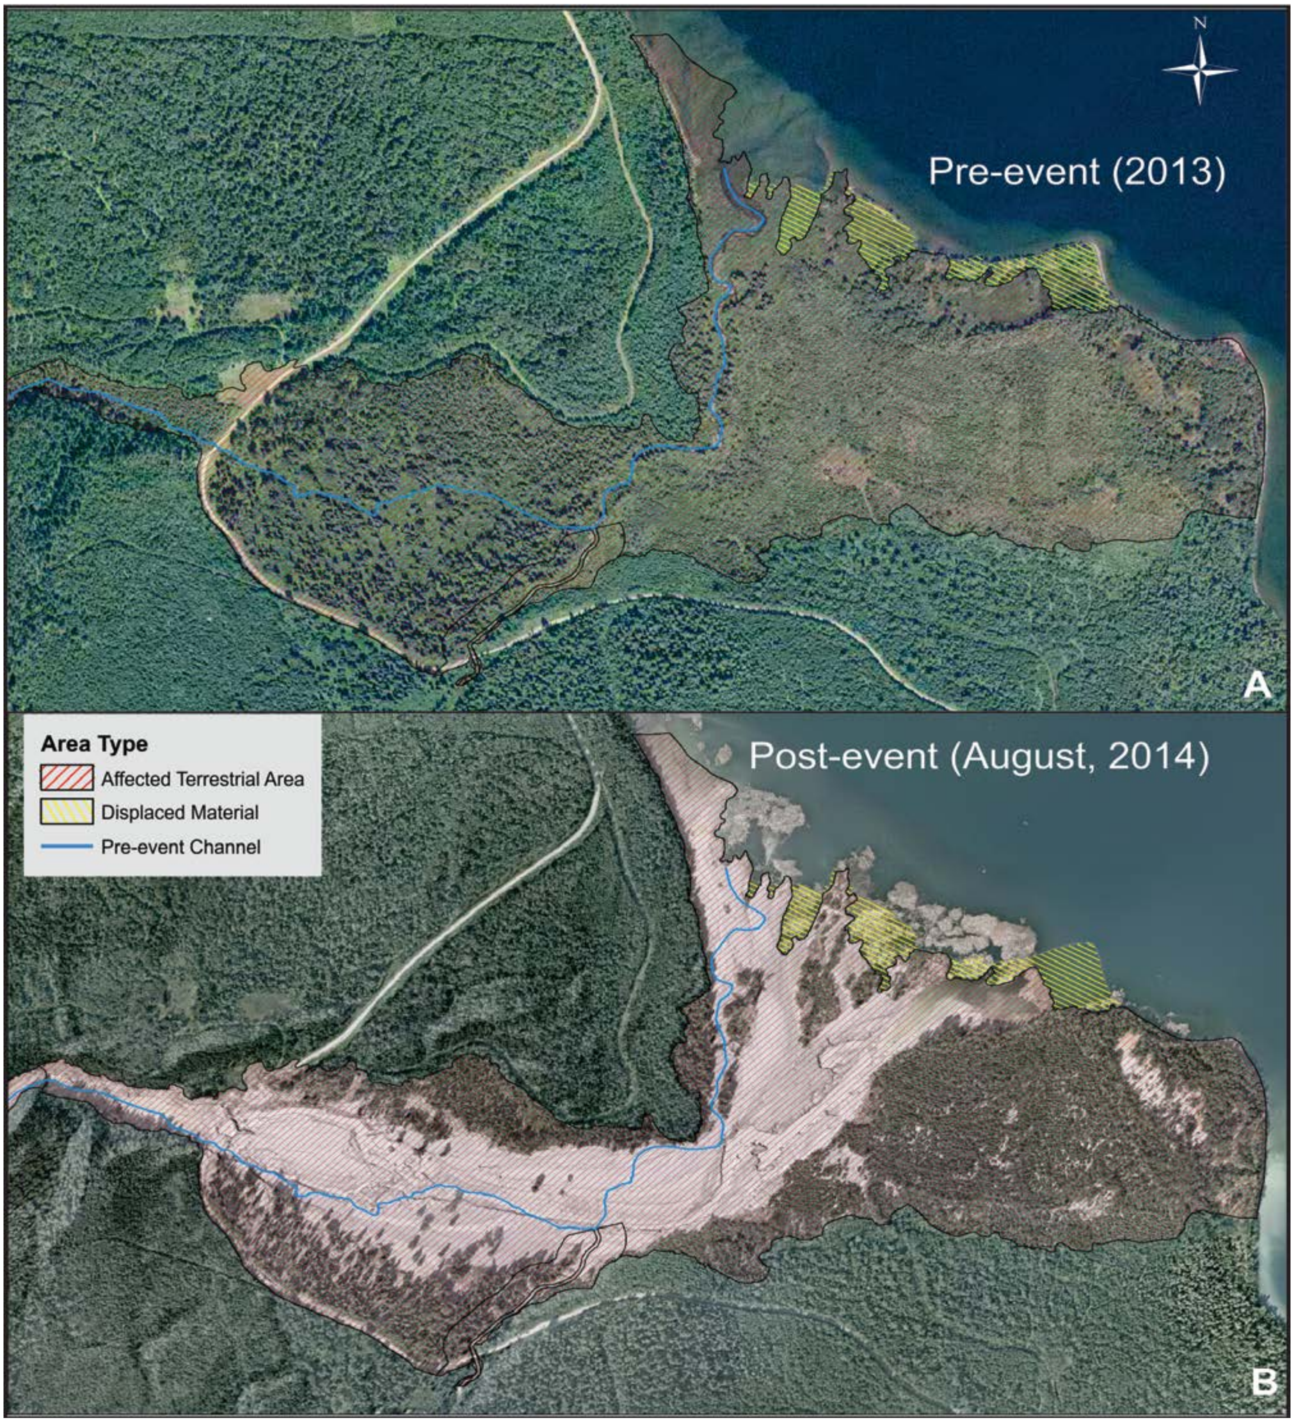

Figure 5-2: Pre- (A) and post-event (B) view of Hazeltine Creek delta

5.2 Key Geomorphic Results

As with the discussion of the pre-event channel and floodplain geomorphology, the five areas defined in the report introduction will be used for consistency in reporting. Key geomorphic characteristics from the analysis of the post-event channel and floodplain are presented in Table 5-2.

Table 5-2: Summary of post-event key geomorphic results

Geomorphic Indicator	Area					Total
	Plug	Upper Hazeltine Creek	Canyon Hazeltine Creek	Lower Hazeltine Creek	Edney Creek	
Terrestrial affected area (m^2)	171,800	1,352,900	47,400	780,000	22,600	2,374,700

Note: (1) average of cross-sectional mean values for maximum elevations; (2) absolute maximum erosion depth value within the area; (3) estimation within the terrestrial affected area. This value does not include the area that was displaced to Quesnel Lake in Lower Hazeltine Creek area.

Post-event Hazeltine Creek was divided into reaches as defined by Minnow Minnow Environmental Inc. (2007). However, the event altered the channel and floodplain morphology of the pre-event channel reaches and necessitated reaches HC-R4 and HC-R5 to be divided into homogeneous units. The resulting post-event reaches are HC-R4a and HC-R4b; HC-R5a and HC-R5b. In addition, two reaches (HC-R0a and HC-R0b) were added upstream of the uppermost reach (HC-R1), but below the Plug area. The post-event channel characteristics are presented in Table 5-3.

Table 5-3: Summary of post-event channel physical characteristics

1. HC-R0a not included as it is not within the pre-event channel area.

The long profile of the post-event channel thalweg displays several high slope knickpoints followed by low slope zones (Figure 5-3). Most of the knickpoints are located in the Upper Hazeltine Creek section within reaches HC-R4b and HC-R5. The slope of the post-event thalweg is relatively stable until the first large knickpoint located in reach HC-R4. Slope increases in the Hazeltine Creek Canyon section. Slope then decreases in Lower Hazeltine Creek toward Quesnel Lake.

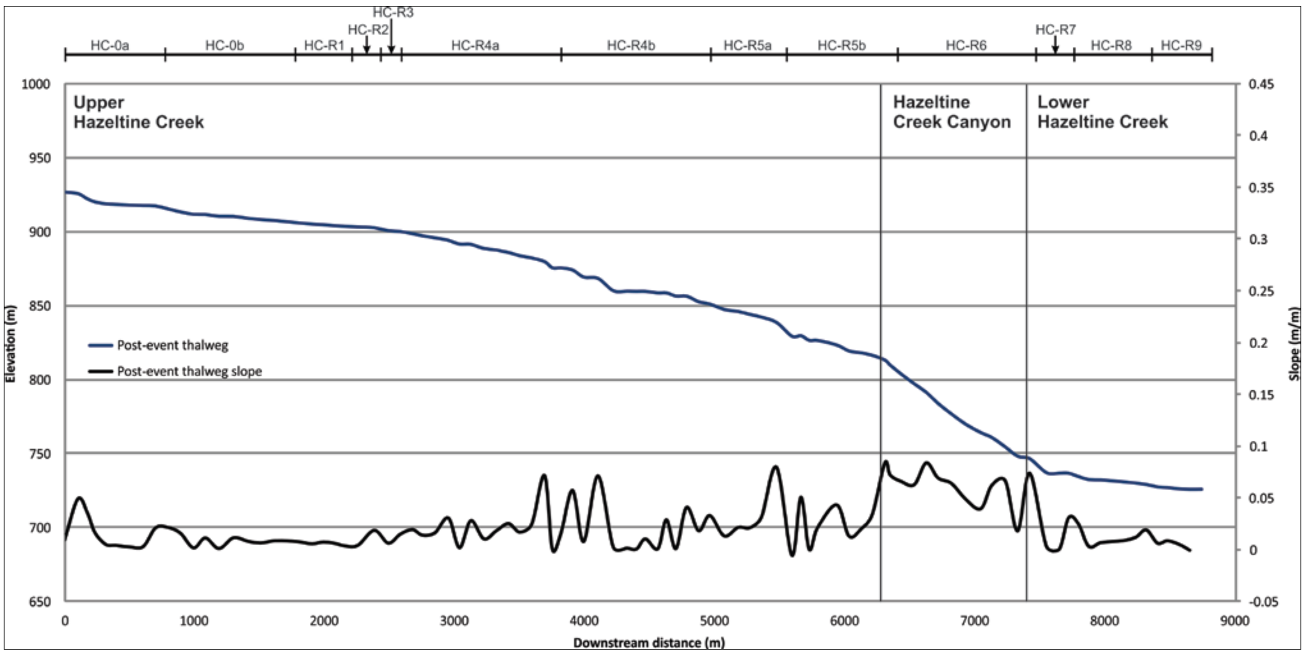

Figure 5-3: Downstream long profile of the post-event thalweg elevation and the thalweg slope

Surficial geology of the study area predominantly reflects glacial processes of the Fraser Glaciation in the Late Wisconsin period (Bichler and Bobrowsky, 2003). Native deposits identified in the field consist of thick blankets of till (~ 42%), glaciofluvial and fluvial sediments on terraces and floodplains (~ 39%), glaciolacustrine and lacustrine material on steep slopes (~ 4.2%) and exposed bedrock (2.8%). Other materials (anthropogenic and colluvial) comprise ~ 12% of the mapped area. Native deposits correlate with the stratigraphic sequence described by Clague *et al.* (1990) and Bichler and Bobrowsky (2003). These materials are covered or mixed with veneers and blankets of tailings.

A summary of tailings deposits and native materials identified in the study area are described in Table 5-4 and Appendix E.

Table 5-4: Summary of typical tailings deposits and native material encountered in the area

Surficial Material	Areas	Surface Expression	Symbol	Description
Tailings	PP, UHC, CHC, LHC, LEC	Thin veneer (x) and veneer(v)	sTb, sTv, sTx	Fine-grained, well sorted and stratified red layer of sandy tailings. Soil particle sizes vary from sand to sandy –loam. These deposits typically occur at the edge of the post-event channel and on top of channel bars. Sediments deposited within the channel are being mobilized by Hazeltine Creek.
	PP, UHC, CHC, LHC,	Thin veneer (x), veneer(v) and blanket (b)	zcTv	Stratified gray layer of highly saturated silty-clay and silt-loam tailings.
Anthropogenic	UHC	Blanket(b)	A	Rock fill and fill from displaced embankment material.
Undifferentiated (U)	PP, UHC, LHC	Blanket(b)	U	LWD deposits mixed with tailings and native soil. Typically occurs at wide overbank areas. Percentage of tailings and native material is varied and difficult to determine.
Organic	PP	Plain(p)	O	Soft, saturated organics overlying lacustrine deposits of fine-grained sand, silt and clays. Located at outlet of Polley Lake.
Till	PP, UHC, CHC, LHC	Blanket(b)	Mb	Massive, matrix supported and poorly sorted deposit composed of various lithology clasts. Clasts are rounded to sub-angular in a very stiff to hard sandy silt matrix. Independent Expert Engineering Investigation and Review Panel (2015) interpreted this as possible ablation till. Till is the dominant native material in the study area.

Table 5-4 (Cont'd): Summary of typical tailings deposits and native material encountered in the area

Surficial Material	Areas	Surface Expression	Symbol	Description
Bedrock	UHC, CHC	Hummocky (h)	R	Exposed bedrock was visible along the channel bed and valley walls during the field investigation. Bedrock type was not identified.
Fluvial	UHC, LEC, LHC	Plain(p), terrace (t)	Fp, Ft	Remnants of recent fluvial material transported by Hazeltine Creek located on pre-event floodplain. Deposits are moderately sorted, sandy to pebbly, sub-rounded to rounded clasts.
Glaciofluvial	UHC, LEC, LHC	Terrace (t), fan(f)	F^G	Glaciofluvial sediments on fan and wide terraces composed of gravely to cobbly material with a sand matrix. Deposits are clast supported, rounded to sub-angular and mixed lithology.
Colluvial	UHC, LEC, LHC	Blankets(b) and veneers(v)	C	Colluvial materials identified in the field are from four different sources: 1) Products of bank failures on till and glaciolacustrine steep slopes. These deposits typically occur at the bottom of banks and within channel; 2) Matrix supported and poorly sorted, debris flow deposit composed of a mix of tailings and native materials; 3) Poorly sorted, clast supported, rounded to sub-angular hyperconcentrated flow deposit composed of a mix of tailings and native material; and, 4) Blocks of rounded massive till transported by the flow. Blocks vary in size (diameter greater than 90 cm were measured in the field).
Glaciolacustrine	UHC, LEC, LHC	Blanket(b), Steep slopes (s)	L^G	Two types of glaciolacustrine materials were encountered in the area: 1) Grey, firm, thinly laminated clay and silty-clay deposits located at the distal zone of Hazeltine Creek. 2) Grey-brown, massive, very stiff (inferred) and no evident structure.

Slope failures occurred at different locations along the debris flow path. Highly unstable and unstable areas (defined in Table 5-5) are located in the Upper and Lower Hazeltine Creek section. At Upper Hazeltine Creek, slope failures occurred at steep sections (greater than 20°). Slopes remain unstable after the event, displaying long and deep (>50 cm) tension cracks and multiple tilting blocks. These features indicate that further slope failures are likely in the near future. The unstable area identified at reaches HC-R1 and HC-R2 in Upper Hazeltine Creek corresponds to fluvial materials affected by gully and rill erosion.

At Lower Hazeltine, unstable and highly unstable areas are related to bank failures occurring on glaciolacustrine steep banks. A summary of slope stability classes is presented in Table 5-5. A color coded map indicating slope stability classes is shown in Appendix G.

Table 5-5: Slope stability of valley walls

Terrain Stability Class	Stability Score	Description	Plug (%)	Upper Hazeltine Creek (%)	Canyon Hazeltine Creek (%)	Lower Hazeltine Creek (%)	Edney Creek (%)	Total Terrestrial Affected Area
I (Stable)	0 - 4	No significant slope failures or erosion problems exist or are expected following the 2014 event.	6.9	80.3	1.7	10.4	0.7	34
II (Slightly unstable)	5	There is a low spatial likelihood (less than 30%) of slope failures or erosion following the 2014 event.	9.5	38.9	0.7	49.6	1.3	50
III (Moderately unstable)	6	Erosion problems along gullies and rills can develop after the 2014 event. There is a moderate spatial likelihood (30% - 50%) of slope failures or erosion following the event.	1.7	63.2	11.2	23.8	0.1	10

Terrain Stability Class	Stability Score	Description	Plug (%)	Upper Hazeltine Creek (%)	Canyon Hazeltine Creek (%)	Lower Hazeltine Creek (%)	Edney Creek (%)	Total Terrestrial Affected Area
IV (Unstable)	7 - 8	Expected to contain areas with a high spatial likelihood (50% to 75%) of developing slope failures or erosion problems following the 2014 event.	-	83.6	1.3	15.1	-	4
V (Highly unstable)	9 -11	Terrain is currently unstable and is expected to contain areas with a very high spatial likelihood (> 75%) of slope failure initiation (or reactivation) and erosion problems following the 2014 event. Slope failure indicators in this class include: active landslides (initiations zones), gully erosion and rills, tension cracks.	-	76.4	-	23.6	-	2

5.3 Plug Area

5.3.1 Key Features

- Removal of floodplain vegetation; and,
- Thick deposits of tailings blocking the outlet of Polley Lake.

5.3.2 Geomorphology

The Plug area is defined by the deposition of material near the Polley Lake outlet. The affected area is approximately 171, 800 m^2.

The debris flow travelled from the TSF downhill towards Hazeltine Creek and Polley Lake, covering a swath approximately 350 m wide and filling a portion of the south end of Polley Lake and upper portion of the Hazeltine Creek channel and floodplain with mixtures of tailings, embankment material, and eroded native material. This material plugged the outlet of Polley Lake (the plug) (Figure 5-4).

The former Hazeltine Creek channel is no longer evident. The upstream end of the decommissioned diversion ditch, dug in the late 1890's (Mulvihill et al., 2005), that diverted water from Polley Lake to the Bullion Pit for hydraulic mining is located within the Plug area. Water from Polley Lake filled the upstream end of the diversion ditch (Figure 5-5).

Evidence of erosion within the Plug area includes the absence of trees and wetland vegetation seen in the pre-event aerial photographs. Scour was limited in several areas within the Plug including where trees remain in situ, one "tree-island" located at Polley Lake (Figure 5-4) and toppled in situ trees located on the western shore of Polley Lake, between the "tree-island", remaining vegetation and in situ organic layers (Figure 5-6).

Typical pre-existing materials encountered in this area consisted of soft, saturated organics overlying lacustrine deposits of fine-grained sand, silt and clays (Polley Lake shore) (KP, 1995) and hard, low permeability silty, clayey glacial till. Deposited tailings included both, gray silty-clay tailings and red sandy tailings. Tailing layers were completely saturated during field investigations. At some soil pit locations the gray and red tailings layer were clearly differentiated.

Some of the greatest volumes of deposition occurred in the Plug area due to proximity to the TSF dam and the relatively low slope of the Plug area. In the field, safe access to the Plug area was limited by the high water content within deposited materials. The volume of deposition is estimated to be within 0.5 Mm^3 and 0.6 Mm^3.

There are no unstable slopes within the plug area. Hydraulic modeling was not conducted in the Plug area because no post-event channel exists there.

Figure 5-4: Deposition within the Plug area looking East across the Polley lake post-event shoreline (September 22, 2014)

Figure 5-5: Nineteenth century diversion ditch containing water from Polley Lake within the Plug area looking down valley at the post-event shoreline (September 22, 2014)

Figure 5-6: Photograph showing in situ toppled trees near Polley Lake in the Plug area

5.4 Upper Hazeltine Creek

5.4.1 Key features

- Removal of floodplain vegetation;
- Zones of deep channel bed erosion;
- Knickpoints within the channel bed;
- Thin spatially heterogeneous deposits; and,
- Unstable slopes adjacent to the channel.

5.4.2 Geomorphology

Upper Hazeltine Creek represents the area from the TSF dam downstream to the beginning of the Hazeltine Creek Canyon. The total affected area is approximately 1,352,900 m^2. Upper Hazeltine Creek is the longest and most complex section of the debris flow, containing a newly formed channel originating at the TSF dam failure site and continuing through the Hazeltine Creek floodplain, knickpoints, flow bifurcation and bank failures.

The mean thalweg slope for the Upper Hazeltine Creek channel is 1.8 %; however, the slope ranges from near vertical to flat. Evidence of erosion within Upper Hazeltine Creek includes the absence of trees and wetland vegetation seen in the pre-event aerial photographs. Five tree islands are located in the first ~ 1,400 m downstream of the TSF dam failure site.

Upper Hazeltine Creek is divided into reaches modified from those defined by Minnow (2007) (see Appendix HIA-A002 and HIA-A003). One reach with two sub-reaches (HC-R0a and HC-R0b) was added to those defined by Minnow:

1) HC-R0a – the section between the TSF dam failure site and the former Hazeltine Creek floodplain (approximately the limit of the Plug); and,

2) HC-R0b - the section between the plug and the upstream limit of HC-R1.

The longest reach defined by Minnow (HC-R4) was divided into two sub-reaches (HC-R4a and HC-R4b).

1) HC-R4a is located between the Gavin Lake road bridge and the upstream most large knickpoint in HC-R4; and,

2) HC-R4b is located between the upstream largest knickpoint in HC-R4 and HC-R5a.

The reach downstream of HC-R4 defined by Minnow (HC-R5) was divided into two sub-reaches (HC-R5a and HC-R5b).

1) HC-R5a is located between the downstream end of HC-R4b and the entrance to a wide and laterally unstable section of valley; and,

2) HC-R5b is located between HC-R5a and HC-R6.

Reaches HC-R1 to HC-R3 are described together due to their similarities in morphology as are reaches HC-R4b and HC-R5a.

5.4.2.1 HC-R0a

The debris flow eroded a swath ~ 350 m wide through this reach through the formerly forested wetland area downslope of the TSF dam. Two (2) new channels were cut into native material. The channels merge near the location of the pre-event Hazeltine Creek channel. The larger 42 m wide channel curves to follow the pre-event channel location. The slope of the thalweg decreased downstream of the TSF dam failure site. The slope of channel ~ 320 m nearest the breach was 0.028 m/m. The slope decreased to 0.0036 m/m for the following 400 m downstream.

One (1) remnant tree island remains ~ 325 m downslope of the dam failure site and two (2) individual in situ trees stand further downslope. Deposition occurred on the edge of the flow, within the area that remains forested and between the forested area and the larger channel on the inside of the channel curve.

Nearer to the TSF and west of Hazeltine Creek, the terrain is slightly eroded compared to pre-existing ground, or slightly above original ground elevation due to deposition. Typical surficial materials encountered in this area consist of anthropogenic material (material displaced from the dam consisting of rock and till fill), native till, large woody debris, tailings and a mix of tailings and anthropogenic material (Figure 5-7).

Hydraulic modelling was not conducted in this section because it is not part of the pre-existing Hazeltine Creek channel.

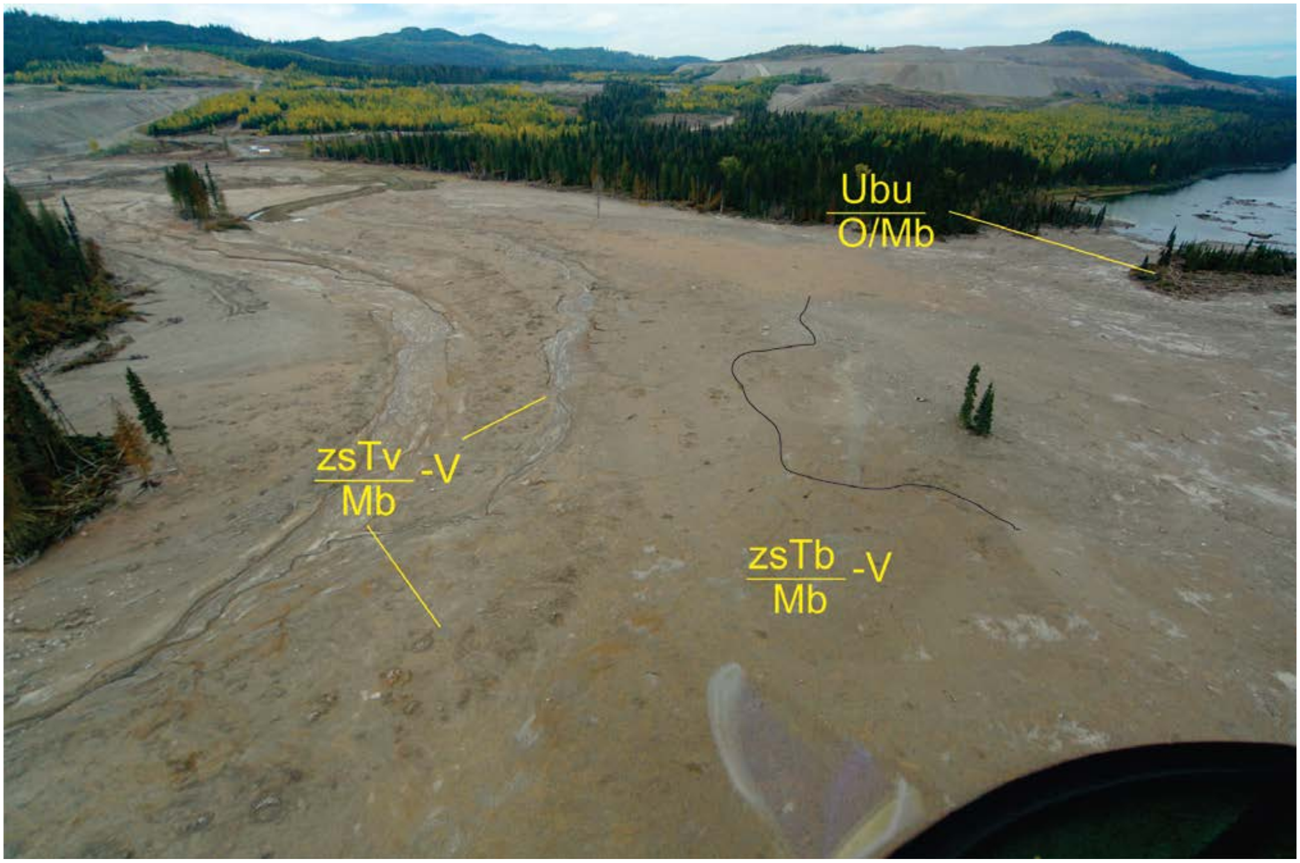

Figure 5-7: Deposition and surficial material at reach HC-R0a (September 22, 2014)

5.4.2.2 HC-R0b

After joining the pre-event Hazeltine Creek floodplain, the debris flow continued downstream of the Plug within the Hazeltine Creek floodplain. The average slope of this section is 0.95%. Water from Polley Lake has been pumped from Polley Lake into Hazeltine Creek at a location approximately 1,300 m upstream of the Gavin Lake Road crossing.

The post-event channel largely follows a similar path to the pre-event channel in this section (Figure 5-8). The post-event channel curves before and after it flows between two small tree islands similar to the pre-event channel geometry. Four (4) remnant tree islands are located between the downstream end of the Plug and the next ~ 800 m. These tree islands created bifurcations within the debris flow. The largest of these is ~ 370 m long and 170 m wide, with LWD accumulated at the upstream end of the tree island. Material was deposited around the trees in these areas.

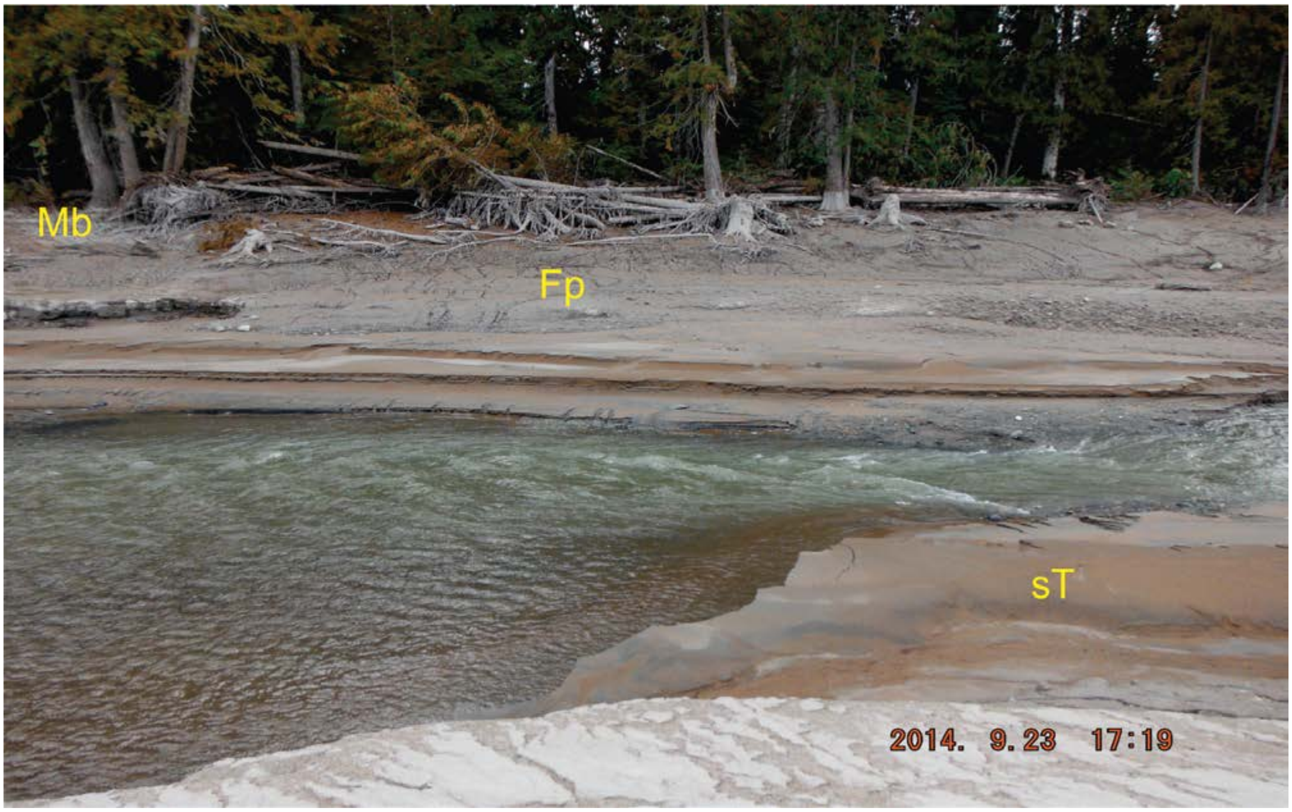

Figure 5-8: Surficial material at HC-R0-b (September 23, 2014)

Beside the largest tree island, the post-event main-channel is located in the right channel of the debris flow near the original channel location. Within this section, a 1.0 m tall knickpoint occurs on the bed of Hazeltine Creek located ~ 1200 m downstream of the TSF dam failure site. The channel abruptly curves (~ 90°) 80 m downstream of the knickpoint. For ~ 250 m, the knickpoint vertically eroded into native material through headcut migration creating a deeper channel downstream of the knickpoint compared to upstream of the knickpoint. Upstream migration of the knickpoint and lateral erosion at the outside of the bend formed ~ 6 m tall near vertical bank. This is an area of continued instability within the bed and bank.

Between the downstream end of the largest tree island and HC-R01, the channel is ~ 100 m wide, shallow and relatively flat. The channel is defined by a lack of trees and limited thickness of deposits. Vertical erosion by the debris flow was limited in this area and no knickpoints occur.

The post-event bankfull channel is 8 m wide and 18 cm deep (Table 5-3), as estimated by the two-dimensional hydraulic modelling results of the MAF discharge. Detailed geomorphological data for HC-R0b is unavailable prior to the event. The deepest pool in the post-event reach occurs immediately downstream of the knickpoint. Smaller pools occur downstream of the large pool. The highest velocity and shear stress values occur at the knickpoint and the section immediately downstream of the large pool. Bed degradation is expected to continue at the knickpoint while the rest of the reach is more stable. Pool depth increases with discharge from the MAF to the 100-year flow.

Slopes are stable except for a steep eroding bank located outside of a meander bend 80 m downstream of the knickpoint (Figure 5-9).

Figure 5-9: Photo shows slope failures at reach HC-R0b and red tailings deposited within the Hazeltine Creek channel (September 23, 2014).

5.4.2.3 HC-R1 to HC-R3

The main debris flow channel is ~ 100 m wide, shallow and has a relatively flat slope in the section (HC-R1 to HC-R3) between the downstream end of HC-0b and the Gavin Lake road bridge (Figure 5-10). The channel is defined by a lack of trees and limited thickness of deposits. Vertical erosion by the debris flow was limited in this area and no knickpoints occur.

Figure 5-10: Hazeltine creek channel in reaches HC-R1 to HC-R3 (September 22, 2014)

Hydraulic modelling of the MAF show the channel to be 15.6 m to 17.4 m wide and 18 - 21 cm deep wider and shallower than the pre-event channel that was 7 m to 7.9 m wide and 36 cm to - 38 cm deep (Table 4-1). The beaver dam and pond present in pre-event HC-R2 is absent from the reach. Generally, the reach displays a homogenous pattern of depth, velocity and shear stress with the exception of high velocities and shear stresses seen immediately upstream of the Gavin Lake Road bridge abutments. Generally, depth, velocity and shear stress values increase as discharge increases from the MAF to the 10-year and 100-year flow. Channel width remains stable as discharge increases resulting from the shape of the debris flow channel it flows within.

5.4.2.4 HC-R4a

The debris flow channel width varies from 15 to 35 m. This section is defined by vertical and lateral instabilities. The post-event channel reach HC-R4a is 1,247 m long and located immediately downstream of Gavin Lake Road. Channel slope is 1.76%. The active wetted channel width during the field investigation varied between 1.5 to 10 m along the reach. Within this section, the debris flow travelled rapidly eroding several meters into native material (Figure 5-11). As a result, the post-event channel displays different morphologies controlled mainly by changes in bed slope and channel bed substrate.

At wide sections, the channel displays braided riffle-pool morphology with extensive, mid-channel bars. Bars are composed of gravel (native material) with a veneer of tailings on top. In narrower sections, channel morphology is characterized by steep, entrenched step-pools. The channel bed is unstable and presently incising. Substrate channel material is mainly gravel, sandy tailings (braided riffle-pool) and eroded till (entrenched step-pool).

Figure 5-11: Eroded till zones within reach HC-R4a. Figure shows depth of scour and unstable slopes following the debris flow (September 24, 2014)

Banks are nearly vertical and unstable at several locations. Debris falls and topplings are the most common slope failures found in the reach caused by the destabilization of the slope that resulted from the debris flow (Figure 5-12). Soil topples are composed of clayey till that disintegrate as they enter into the channel contributing volumes of fine, suspended sediments to Hazeltine Creek flows. Banks were actively failing at the time of site investigation. Slope changes were evident within several hours during field inspections. Ongoing undercutting at incised sections of the channel is the main cause of ongoing slope failure. This condition will persist until the bank reaches a stable slope angle. High flow events have the potential to increase the rate of retrogression of these vertical banks (Figure 5-12). Deep and long tension cracks are evident on both left and right banks (Figure 5-12), indicating future retrogression.

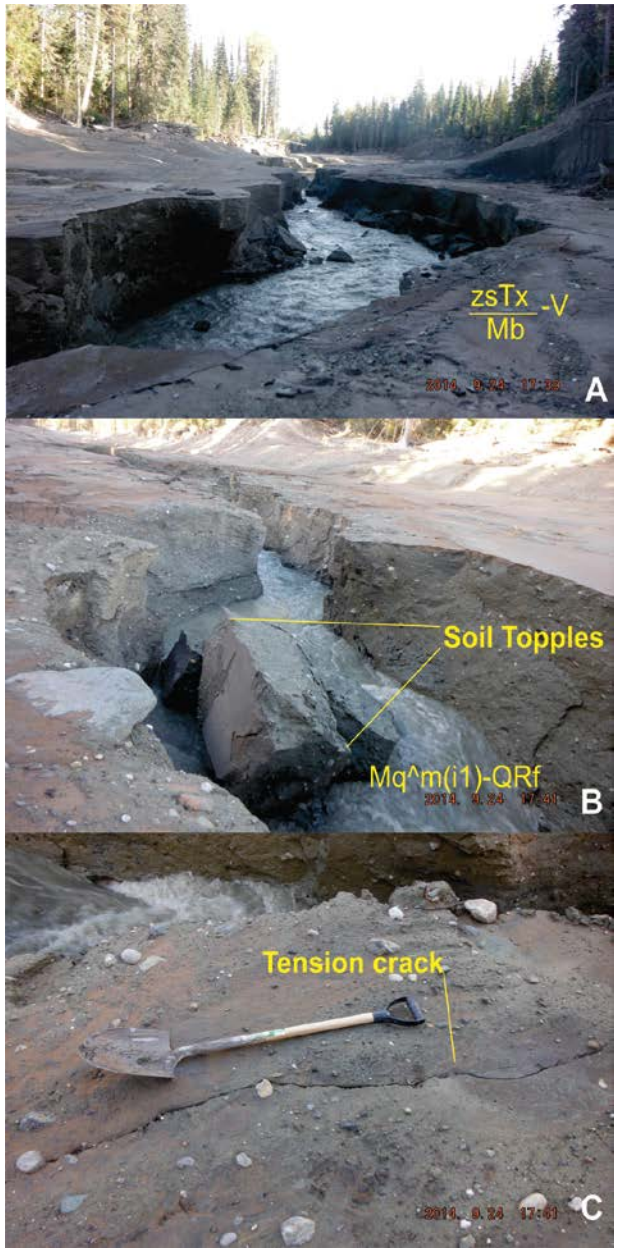

Figure 5-12: Slope failures at HC-R4a. A - shows the extension of slope failures on both banks. (Symbol is a silty-sandy thin veneer of tailings overlying a morainal blanket modified by overland erosion (-V)). B- Topples entering into the channel. Channel bed is composed of till (M). C- Long tension crack on right bank.

Hydraulic modelling of the MAF predicts the post-event channel in HC-R4a to be 15.1 m wide and 20 cm deep, wider and shallower than the pre-event channel that was 4.7 m wide and 43 cm deep (Table 4-1). The reach displays a pattern of lower depth, higher velocity and higher shear stress zones alternating with higher depth, lower velocity and lower shear stress zones likely related to the development of riffles and pools within the channel. Higher velocities meander from side to side in the channel in the lower end of the reach, indicating incipient meandering similar to the process described by Lewin (1978). The highest velocities within the reach occur where the channel narrows. These areas will likely widen due to the higher shear stresses resulting from the high velocities. Generally, depth, velocity and shear stress values increase as discharge increases from the MAF to the 10-year and 100-year flow. Generally, channel width remains stable as discharge increases resulting from the shape of the debris flow channel it flows within.

5.4.2.5 HC-R4b and 5a

The post-event reaches R4b and R5a are 1191.6 m and 596.6 m long, respectively. They are similar and are reported on together. These reaches are defined by two major knickpoints located ~ 2.5 and 2.0 km upstream of the Hazeltine Creek Canyon. The knickpoints are 6 m and 10 m in height, respectively (Figure 5-13). The channel narrows and steepens in this section, and displays a braided, riffle-pool morphology along most of its length. Bed material is mainly composed of sandy tailings. Banks are composed of sandy-pebbly fluvial, sandy-cobbly glaciofluvial, clayey till and glaciolacustrine material. A thin veneer of sandy tailings (less than 10 cm) covers the top of both banks.

Slope failures are extensive and are located at till and glaciolacustrine banks with slopes greater than 15°. Soil and debris falls are the most common mechanism of failure. Indicators of active slope failures include fallen and tilted soil blocks, fallen trees, overhanging root mats and tension cracks. High discharge undercutting at the base of these steep banks may increase the current failure rate. Steep glaciolacustrine slopes and walls at major knickpoint features are the best examples of these unstable areas (Appendix HIA-H-006 and Figure 5-14).

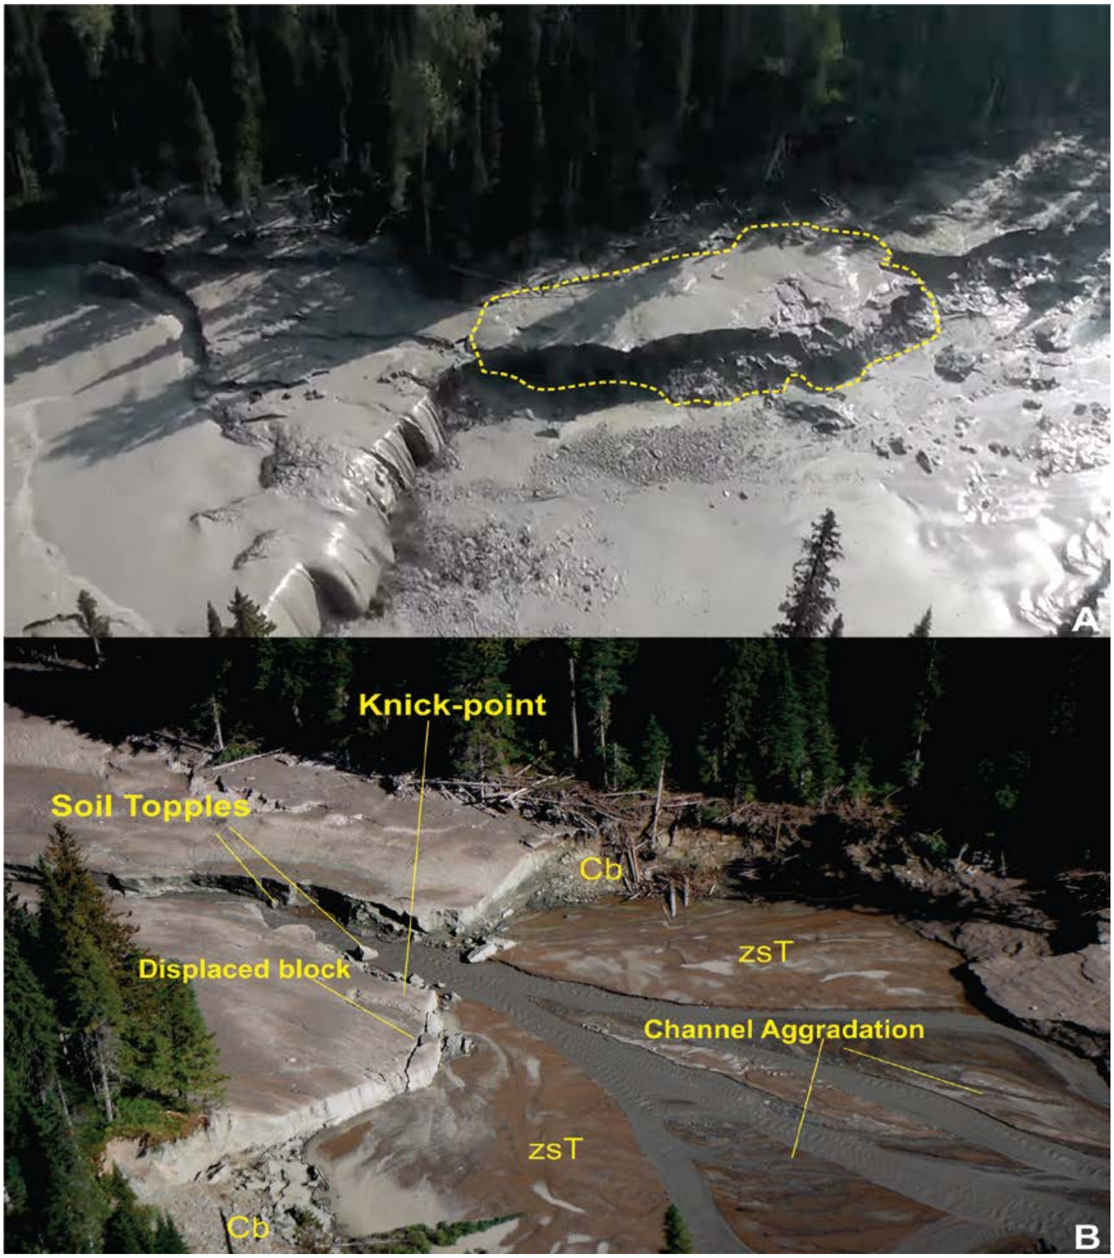

Figure 5-13: Knickpoint located 2.5 km upstream of Hazeltine Creek Canyon (HC-5a). A - Screen-shot taken from the Cariboo video. The yellow dashed line indicates material that was mobilized at a later stage of the event. B- Figure shows slope failures on both banks. Deposits of tailings (zsT) are estimated to be deeper than 1 m on both edges of the active channel.

Figure 5-14: Slope failures at reach HC-R4a and HC-R4b. A- Figure shows extension of bank failures on right bank and location of sandy tailings. B – Figure shows extension of bank failures on left bank.

Hydraulic modelling of the MAF predicts the post-event channel in HC-R4b and HC-R5a to be 22.7 to 23.3 m wide and between 22 and 26 cm deep, wider and shallower than the pre-event channel that was 4.5 to 4.7 m wide and 38 to 43 cm deep (Table 4-1). A deep (~ 80 cm) and long (~ 100 m) pool occurs between the large knickpoints. A wide and shallow pool created by the upstream migration of the knickpoint occurs downstream of the second knickpoint. An additional smaller knickpoint, and associated downstream pool, occurs downstream of the second large knickpoint. Velocity and shear stress values are highest at knickpoints and high slope sections. These sections have experienced down-cutting following the event and erosion is predicted to continue. The area of channel exposed to erosive shear stresses and velocities increases with higher discharge. The channel width generally remains stable as discharge increases due to the steep side slopes and channel banks.

5.4.2.6 HC-R5b

Reach HC-R5b in Upper Hazeltine Creek is characterized by a 900 m long and 100 m wide debris flow channel that narrows for approximately 30 m (bedrock canyon) and then widens downstream until it reaches the canyon section. The channel displays both step-pool and riffle-pool morphologies. From the short bedrock canyon downstream to Hazeltine Creek Canyon the debris flow eroded and scoured extensive wide sections. The floodplain and glaciofluvial terraces were eroded by the debris flow. Bedrock is exposed at some locations (Appendix HIA-H-007). Channel morphology is mainly controlled by changes in bed slope and/or changes in substrate material. Channel bed material is varied composed primarily of bedrock, till and a thin layer of tailings.

Post-event banks are composed of different materials, including sandy fluvial, sandy-cobbly glaciofluvial and bedrock. Thin veneers and veneers of sandy tailings cover the top of the channel banks. At wide sections within this reach, the channel includes extensive bar deposits consisting primarily of gravel and sandy tailings. At narrow sections, the channel is entrenched and currently incising into native material. Extensively scoured zones, slope failures and eroding banks are the typical field indicators of channel disturbance identified in the area.

Slopes within this reach show clear signs of active slope failures. At ~ 590 m upstream of Hazeltine Creek Canyon there is a wide section, immediately downstream of the short bedrock canyon that experienced focused scour and erosion. The section extends for about 250 m with very steep slopes (40°) on the left bank and moderately steep slopes on the right bank (15°). The left bank is composed of glaciolacustrine material and shows indicators of active slope failures (i.e., wide and deep tension cracks, tilted and toppling blocks, overhanging root mats) (Figure 5-15). A blanket of colluvial material was observed covering ~1742 m^2 of the toe of this steep section.

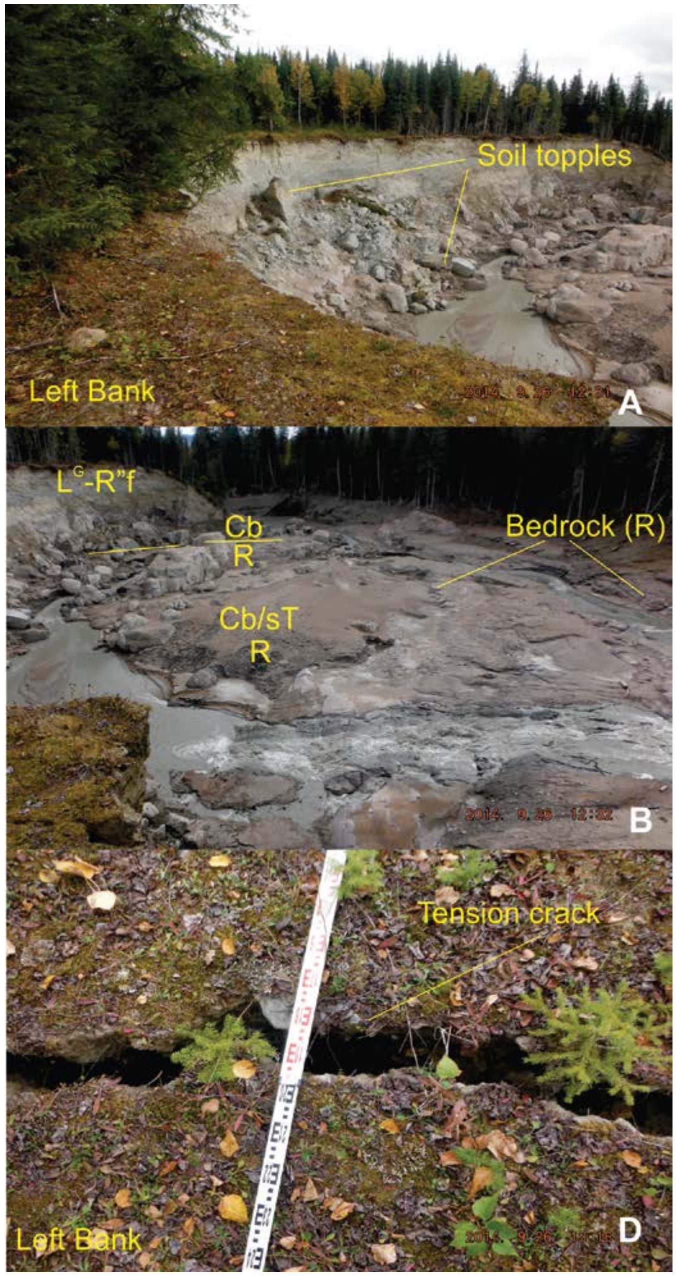

Figure 5-15: Wide scoured and eroded section downstream of short length bedrock canyon in HC-RC5b. A- Figure shows a vertical glaciolacustrine banks with fallen blocks and topples. B- Location of exposed bedrock and identified surface material. C-Shows 10 cm wide tension crack on left bank.

Hydraulic modelling of the MAF predicts the post-event channel in HC-R5b to be 22.6 m wide and 32 cm deep, wider and shallower than the pre-event channel that was 4.5 m wide and 38 cm deep (Table 4-1). A deep pool is located beside the unstable right bank of the creek and deeper sections also occur where the channel narrows. High shear stress and velocity values are concentrated locally at a knickpoint. Shear stress and velocity increase between the MAF and 10-year flow but decrease due to back flooding at the 100-year flow. As with the other sections, the channel width is generally stable.

5.5 Hazeltine Creek Canyon

5.5.1 Key features

- Removal of vegetation;
- Channel bed erosion; and,
- Thin tailings deposits.

5.5.2 Geomorphology

The Hazeltine Creek Canyon (HC-R6) is the steepest section of the channel. The affected area is approximately 47,400 m^2 (Figure 5-16). Geomorphologic impacts from the debris flow are related to removal of vegetation and erosion of the channel bed (Figure 5-17).

Hazeltine Creek Canyon was a ~ 1020 m long pre-existing steep and narrow gorge cut into surrounding bedrock. The canyon is not straight but instead meanders with a sinuosity of 1.18. The post-event canyon descends ~ 27 m (from 16 - 49 m) into the Fraser Plateau. Within the canyon the total area affected by the debris flow is ~ 47,400 m^2 and the mean width of the area affected is ~ 31 m, representing the narrowest section of the debris flow path. The post-event Hazeltine Creek Canyon also displays the steepest slope 6.1 %.

The debris flow removed the pre-event Hazeltine Creek channel, vegetation at the base of the canyon and eroded virtually all native material from the canyon (Figure 5-17). The post-event canyon bed and banks are composed of exposed bedrock which controls the morphology of the channel and canyon walls (Figure 5-18).

Reconstruction of the pre-event floodplain elevations within the Hazeltine Creek Canyon was difficult as high shear stresses and erosion removed the pre-event floodplain levels.

Post-event, thin veneers of tailings sand and gravel cover the bottom of the Hazeltine Creek Canyon (Figure 5-19). This is the area with the least deposition. Volumes of deposition are estimated to be less than 0.1 M m^3.

Figure 5-16: Overview of the Hazeltine Creek Canyon (HC-R6)

Figure 5-17: Upstream entrance to the Hazeltine Creek Canyon (HC-R6) (September 26, 2014)

Figure 5-18: Photographs within the Hazeltine Creek Canyon showing exposed bedrock at a narrow section (HC-R6) looking upstream (August 26, 2014)

Figure 5-19: Photograph within the Hazeltine Creek Canyon showing exposed bedrock and a thin veneer of tailings at a wider section (HC-R6) looking upstream (August 26, 2014)

Hydraulic modelling of the MAF predicts the post-event channel in HC-R6 to be 10.3 m wide and 28 cm deep, again wider and shallower than the pre-event channel that was 3.7 m wide and 27 cm deep (Table 4-1). Depth, velocity and shear stress values are more homogeneous within the canyon, with the exception of a wider section in the middle of the reach. High velocity and shear stress zones are localized and related to bed rock topography. Higher shear stresses and velocity values follow the middle of the channel due to the generally symmetrical channel geometry. The channel width generally remains stable as discharge increases resulting from the steep side slopes and channel banks. The bed and banks of the canyon are predicted to be stable due to the exposed bedrock.

5.6 Lower Hazeltine Creek

5.6.1 Key features

- Removal of floodplain vegetation;
- Channel avulsion;
- Zones of deep erosion;
- Knickpoints within the channel bed;
- Thick deposits of tailings and colluvial material; and
- Changes to the Quesnel Lake shoreline.

5.6.2 Geomorphology

Lower Hazeltine Creek includes the channel downstream of the mouth of the canyon to the channel outlet at Quesnel Lake. The affected area, including the displaced material along the Quesnel Lake shoreline is approximately 780,000 m^2. The mean slope of the eroded channel within Lower Hazeltine Creek is 1.6 %. Geomorphological processes evident in this area during and after the debris flow include: erosion and deposition, knickpoints within the channel bed, channel avulsion, and slope and bank failures. After exiting Hazeltine Creek Canyon, the channel within Lower Hazeltine Creek widens and steepens. Identified impacts at this section are related to the development of multiple debris flow paths during the event. From the canyon, the debris flow continued down Hazeltine Creek channel towards the delta and Quesnel Lake eroding till, fluvial, glaciofluvial and glaciolacustrine material and depositing tailings and LWD in wide overbank areas.

The debris flow bifurcated. One portion modified the outlet of Hazeltine Creek at Quesnel Lake. Both erosion and deposition occurred at the shoreline, with erosion of materials, including low sloping deltaic deposits. Deposition of material near the pre-event Hazeltine Creek channel outlet that resulted in a gain of 16,887 m^2 of terrestrial area.

The estimation of terrestrial area gained is linked to corresponding water level of Quesnel Lake Aggradation of the pre-event channel caused the avulsion of Hazeltine Creek. Hazeltine Creek's new outlet is located about 400 meters north-east of its pre-event location.

A second portion of the debris flow, travelled down the creek following the pre-event channel. Both, erosion and deposition occurred along this flow path. Deposition of sandy tailings, silty-clay tailings and LWD resulted in wide, forested overbank areas. Three different types of post-event erosion are evident in this area: channel scour, lateral erosion and overbank erosion (surficial erosion).

Channel scour exposed long sections of glaciolacustrine material situated underneath of glaciofluvial deposits. Maximum average net scour depth was estimated to be within 4.55 m and 5.44 m. Lateral erosion from the destabilization of channel banks is evident along new channel banks. Overland erosion caused the removal of surficial material via rills and gullies.

As the debris flow reached Quesnel Lake it eroded large portions of the shoreline and deposited these materials into the lake. The total displaced material removed at the distal zone of the delta was approximately 32,200 m^2.

Lower Hazeltine Creek is divided into three (3) distinct reaches: HC-R7, HC-R8, and HC-R9.

Figure 5-20: A - Former location of the Hazeltine Creek channel looking downstream (HC-R9).B - Post-event Hazeltine Creek delta near the pre-event outlet (HC-R9).

5.6.2.1 HC-R7

The first reach below the canyon is a ~ 300 m long, steep (3.34%) and contains a large knick point incising into native material (Figure 5-21). The debris flow bifurcated ~ 170 m downstream of the Hazeltine Creek Canyon within this reach. A portion of the debris flow traveled down the left bank eroding into native material and scouring sections up to a maximum of 7 meters deep (Figure 5-22).

Figure 5-21: Knickpoint and origin of debris flow bifurcation located in reach HC-R7

Figure 5-22: Erosion of till material in reach HC-R7 at former Horsefly-Likely Forest Service Road (Ditch Road) bridge location

Hydraulic modelling of the MAF predicts the post-event channel in HC-R7 to be 23.9 m wide and 20 cm deep, wider and shallower than the pre-event channel that was 5.3 m wide and 37 cm deep (Table 4-1). Flow splits (bifurcates) upstream of the knickpoint, creating a confluence in HC-R8 downstream. High velocity and shear stress zones occur at the knickpoint. The area exposed to high shear stresses increases with increasing discharge. The knickpoint is predicted to continue to migrate upstream and downcut.

5.6.2.2 HC-R8

The second reach of Lower Hazeltine Creek (HC-R8) extends ~ 620 m downstream of HC-R7, from downstream of the former location of Horsefly-Likely FSR (Ditch Road) to the confluence of Hazeltine and Edney Creeks. The reach is 620 m long. Slope gradient is 1.18% and bed substrate is now composed primarily of tailings and exhibits riffle-pool morphology. Banks are composed of pebbly-cobbly fluvial and glaciofluvial material. A thin veneer of sandy tailings covers the top of both banks. Two flood channels converge 235 m downstream of HC-R7 (Figures 5-23 and 5-24) and the channel widens and shallows as a result. At wide sections, extensive bar formations occur. Bars are mainly composed of a layer of sandy tailings on top of coarse alluvial material.

Figure 5-23: Overview of reach HC-R8 looking downstream showing bifurcation and confluence of the debris flow. Note eroding slope on the left bank

Figure 5-24: Reach HC-R8 looking downstream showing confluence of the debris flow bifurcation

Hydraulic modelling of the MAF predicts the post-event channel in HC-R8 to be 15.1 m wide and 31 cm deep, wider and shallower than the pre-event channel that was 5.0 m wide and 27 cm deep (Table 4-1). The confluence created by the flow bifurcation in HC-R7 occurs in HC-R8 (Figures 5-23 and 5-24). Higher velocity and shear stress zones occur in narrow sections upstream of the confluence and in the center of the channel upstream of the confluence with Edney Creek. The area exposed to high shear stresses at the knickpoint increases with increasing discharge.

5.6.2.3 HC-R9

The third reach of Lower Hazeltine Creek (HC-R9) is ~ 500 m long between the confluence of Edney and Hazeltine creeks and the outlet at Quesnel Lake (Figure 5-25). This channel displays irregular braided morphology with riffles and pools (Figure 5-26). The morphology changes to an irregular braided channel downstream until the outlet (Appendix HIA-H011). The reach gradient is 0.92%. Channel bed material is mainly composed of sandy tailings. Common field indicators of channel impact at this reach includes: the development of extensive channel bars and multiple channels, deep scoured zones, eroding banks and the presence of LWD.

Figure 5-25: Overview of reach HC-R9 from the confluence of Edney and Hazeltine Creeks

Figure 5-26: The lowest most reach (HC-9) downstream of the confluence with Edney Creek

Pre-existing deposits within Lower Hazeltine Creek section consist of pebbly to cobbly fluvial and glaciofluvial material on terraces and floodplain and lacustrine/glaciolacustrine blankets (Appendix HIA-H-011). Following the event, colluvial material consisting of a mix of tailings and native sediments entrained from the channel bed and banks was deposited at the distal zone of the delta near the shoreline. Deposits of LWD mixed with tailings and coarse material are located on the edges of the debris flow path (Figure 5-27). Material was deposited overbank on the delta within the adjacent forests.

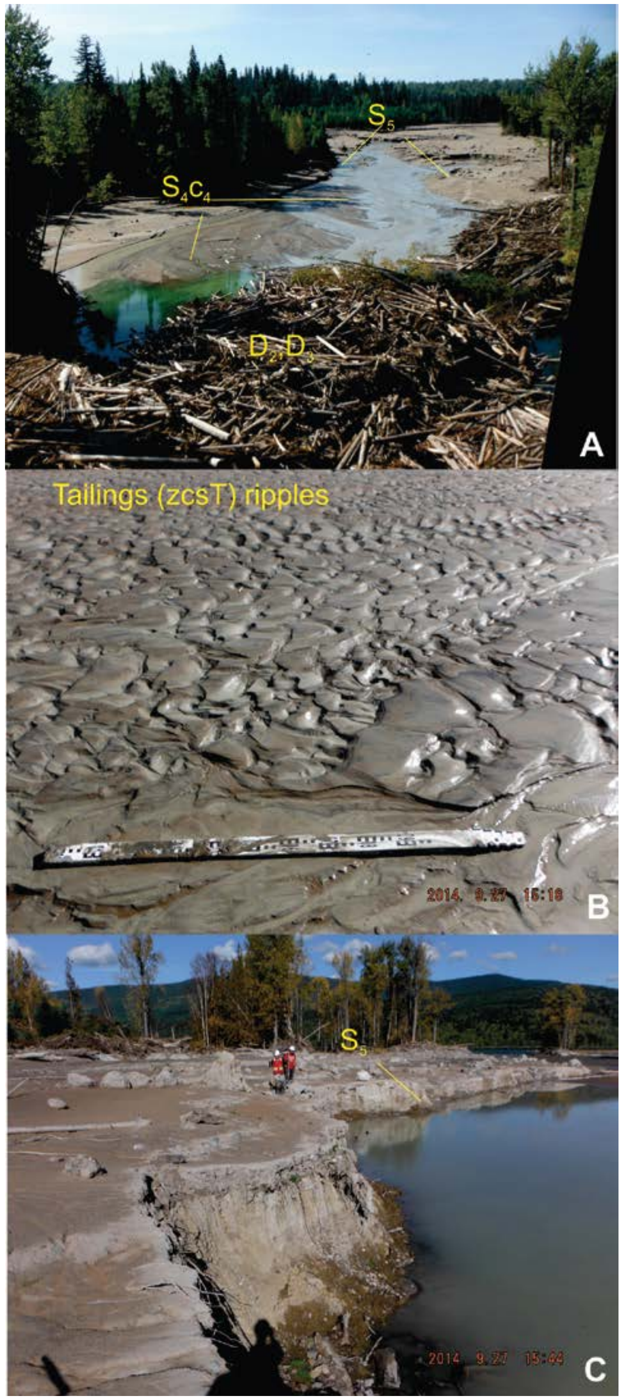

Figure 5-27: A, B & C: Field indicators of channel disturbance at Lower Hazeltine Creek, reach nine (HC-R9)

Within this reach, the post-event channel banks are steep and composed of exposed clayey glaciolacustrine material. Banks are generally unstable, showing evidence of topples and falling blocks into the channel as a consequence of lateral erosion (Figure 5-28). These blocks are contributing fine sediments to Hazeltine Creek discharge. Deep tension cracks are visible along the banks indicating likelihood of continued bank failures in the future. These characteristics extent along the entire exposed glaciolacustrine deposit.

Figure 5-28: A&B – Hazeltine Creek right bank erosion of native glacial lacustrine material (HC-R9)

Hydraulic modelling of the MAF predicts the post-event channel in HC-R9 to be 26 m wide and 28 cm deep, wider and shallower than the pre-event channel that was 11.3 m wide and 43 cm deep (Table 4-1). The channel widens and velocities and shear stresses increase downstream of the confluence with Edney Creek due to the additional discharge. Depth, velocity and shear stresses are more homogeneous in HC-R9. Shear stress and velocity values increase as the channel deepens and with increasing discharge. The channel width does not increase with discharge due to steep banks.

5.7 Edney Creek

5.7.1 Key features

- Removal of floodplain vegetation;
- Channel avulsion;
- Knickpoint at the confluence of Hazeltine and Edney Creek; and,

- Thin spatially heterogeneous deposits.

5.7.2 Geomorphology

Edney Creek mouth comprises the section that extends from the confluence of Hazeltine and Edney Creeks to ~ 500 m up the Edney Creek channel. The affected area is approximately 22,600 m^2. At the downstream section of this reach, Edney Creek is an entrenched (~ 2.5 m deep) riffle-pool channel. The debris flow caused deposition of tailings and colluvial material, channel avulsion and knickpoint erosion on Edney Creek.

A thin layer of sandy tailings was deposited on the Edney Creek floodplain and banks as a result of the debris flow (Figure 5-29). The event forced the Edney Creek channel down valley. The channel confluence moved about 100 m down from the pre-event location. At the new confluence, the area is defined by a knickpoint (Figure 5-30).

Erosion from overland flow occurred on top of the banks. Roots and disturbed vegetation are evident in the area. The right bank of Edney Creek is steep and unstable. Fallen blocks of clayey glaciolacustrine material were observed at the confluence of Edney and Hazeltine Creeks. The left bank is composed of glaciofluvial material and is mainly stable.

Figure 5-29: Post-event Edney Creek channel looking upstream showing tailings deposited within the channel (November 2, 2014)

Figure 5-30: Confluence of Edney and Hazeltine creeks (September 22, 2014)

Hydraulic modelling of the MAF predicts the post-event channel in Edney Creek to be 13.9 m wide and 31 cm deep. Detailed field data on the pre-event morphology of this section of Edney Creek were not found. Upstream of the Horsefly-Likely FSR bridge, the channel is largely unaffected by the debris flow. High velocity riffles and lower velocity pools occur in this zone. Downstream of the bridge, the channel is wider and the velocity and shear stresses are more homogeneous and generally lower than upstream of the bridge. High velocities and shear stresses occur at a knickpoint located just upstream of the confluence of Hazeltine and Edney Creeks. The knickpoint subsequently migrated upstream and degraded (Figure 5-30). At higher flows the channel widens and flows onto the floodplain because, unlike Hazeltine Creek, the post-event area surrounding Edney Creek is largely depositional and not erosional.

6 CONCLUSIONS

The Hydrotechnical and Geomorphological Impact Assessment documents the physical impacts to the channel and floodplain of Hazeltine and Edney Creeks from the debris flow created by the Mount Polley Mine tailings storage facility (TSF) dam failure. The terrestrial area (237.4 ha) affected by the debris flow extends from the failure site downslope to Hazeltine Creek, upstream to Polley Lake and downstream to Quesnel Lake. Historical aerial photographs and information in previous reports were used to document the physical characteristics of Hazeltine and Edney Creeks prior to the event. Impacts of the event were documented through analysis of digital elevation models, aerial photography taken after the event, field assessment, hydraulic modeling, and monitoring of discharge and turbidity following the event.

The pre-event channel and floodplain geomorphology was analysed and a literature review conducted to define the pre-event hydrologic and geomorphic conditions of Hazeltine and Edney Creeks. The creeks are characterized by a nival hydrologic regime modified by historical diversions. Three hydrometric stations were installed following the event to monitor discharge and turbidity. Turbidity results showed sediment production is related to both high erosion rates in Upper Hazeltine Creek above the canyon and rain fall events. Time series analysis conducted on three (3) years of historical aerial photographs (1974, 1996 and 2009) showed the Hazeltine Creek channel was largely stable over the period of record. Changes observed between historical aerial photographs occurred mainly in areas of low slope where beaver dams were reported (Appendices 621717-HIA-B001 to B015).

Impacts of the debris flow to Hazeltine and Edney Creeks were documented through mapping of surficial material, hydraulic modelling, estimation of valley erosion volumes and terrain stability. 10 post-event channel reaches were described using field data. Key hydrological and geomorphological changes observed within the study area were:

- removal of vegetation (1,358,540 m^2 representing 57 % of the total terrestrial affected area);
- widening and shallowing of the channel;
- formation of deep erosion zones (e.g., two large-knickpoint features 6 m and 10 m high located approximately 2.5 and 2.0 km upstream of the Hazeltine Creek Canyon, respectively);
- greater number of channel bars;
- thick deposits of tailings and colluvial material;
- formation of multiple channels and braids;
- creation of eroded and unstable banks;
- increase in LWD (terrestrial area impacted by LWD deposition is 74,275 m^2);

- channel avulsion (e.g., Lower Hazeltine Creek); and,
- changes to Quesnel Lake shoreline (approximately 32,200 m^2 of material was removed at the distal zone of the delta).

Tailings and reworked native materials were deposited within the post-event Hazeltine Creek channel and on the floodplain. Surficial material maps (Appendix 621717-HIA-E001 to E006) classify areas (polygons) with defined material type (tailings and native soil), surficial landforms and geomorphic processes. Typical terrain units in the area include terraces and fans composed of glaciofluvial material, blankets of till and steep valley walls composed of bedrock and glaciolacustrine materials. Two types of tailings (sandy-tailings and silt-loam tailings) were documented within the terrestrial affected area.

The deposition map (Appendix 621717-HIA-E001 to E006) shows thickness of tailings by terrain polygons. 10 deposition intervals are defined ranging from less than 0.1 m to greater than 3.5 m. Total volume of deposition within the terrestrial area is estimated to be between 1.3 and 1.9 Mm^3. Areas of larger volume deposition include the Polley Plug (0.5 to 0.6 Mm^3) and Lower Hazeltine Creek (0.2 to 0.6 Mm^3). A thin veneer of tailings was deposited along the remainder of the channel. These tailings are being quickly mobilized by post-event Hazeltine Creek discharge and largely deposited into Quesnel Lake.

The post-event Hazeltine Creek valley shows evidence of erosion. Main indicators of erosion include: lack of vegetation cover and lack of well-developed soil, exposed bedrock, rills and gullies and knickpoints. Net volume and maximum depth of erosion is estimated based on the difference in elevation between the pre-event floodplain elevation and the post-event surface. Net volume of eroded material is estimated to be between 0.6 and 1.7 Mm^3.

The post-event banks and valley walls of Hazeltine Creek display evidence of slope failures. The slope stability map (Appendix 621717-HIA-G001 to G006) shows a classification of five (5) terrain stability classes and associated processes. Main active processes identified in the area are slope failures in the form of soil toppling and soil/debris falls. A minor extent of overland erosion also occurs. The assigned stability classes range from Class I (no significant slope or bank failures) to Class V (unstable terrain, very high likelihood of slope and bank failures) (Table 5-5). The terrain stability map shows areas with high and very high likelihood to contain or develop slope failures following the event. These areas include slopes greater than 26°. Conditions observed during the field assessment indicate these areas will remain unstable until angle of repose is reached.

To identify areas on the Hazeltine Creek bed susceptible to erosion and deposition, the River2D hydraulic model was used to simulate patterns of inundation extent, depth and velocity and shear stress for the MAF, 10-year and 100-year return intervals. These results show areas where riffles and pools are establishing, and areas of incipient meandering. Areas of high shear stresses, indicating erosion potential, occur at knickpoints and high slope sections in HC-0b, HC-4b, HC-5a and HC-R7. These sections have experienced incision following the event and erosion is predicted to continue. Deep and wide pools with low shear stresses, indicating the potential for deposition, occur downstream of knickpoints. High velocity and shear stress zones in the canyon are localized and related to bed rock topography (Appendix 621717-HIA-F001 to F054).

7 RECOMMENDATIONS AND MONITORING

The plan for mitigating the impacts of the debris flow on Hazeltine Creek are presented within the PEEIAR summary report and will therefore not be discussed here.

The three hydrometric stations were installed by Watersmith Research Inc., (2015). It is recommended that the three hydrometric stations be maintained until hydrology and turbidity levels return to natural background levels.

9 ACKNOWLEGMENTS

This report was written by Leif Burge, M.Sc., Ph.D., P.Ag. (Project Manager) and Vanessa Cuervo, M.Sc., with senior technical review provided by Richard Guthrie, M.Sc., Ph.D. P.Geo and Project Sponsor Gordon Johnson, M.Sc., P.Eng. Other SNC-Lavalin contributors included Hawley Beaugrand, M.Sc., Megan Hendershot, M.Sc., and Cory McGregor, B.Sc. GIT. Faruk Bhuiyan, M.Sc., Ph.D. conducted the hydraulic modelling. Russell Smith, Ph.D., M.Sc., P.Geo. and Patrick Little, M.Sc., A.Ag. from Watersmith Research Inc. contributed to sections on hydrometric stations and analysis of turbidity patterns.

The field program was executed by Leif Burge, Vanessa Cuervo, Megan Hendershot, and Cory McGregor. Additional material depth data was provided by Trevor McConkey, M.Sc., P.Ag. and Daniel Schneider, R.P.Bio., P.Ag., MPMC, and Archer CRM.

10 CLOSURE

This report was prepared based on objectives and available information at the time of writing. Contributions and comments were provided by internal and external geoscientists and agrologists.

Leif Burge, M.Sc., Ph.D., EP, P.Ag.
Senior Scientist – Fluvial Geomorphology
Environment & Water

Vanessa Cuervo, M.Sc.
Geohazards Specialist
Environment & Water

11 NOTICE TO READER

This report has been prepared and the work referred to in this report have been undertaken by SNC-Lavalin Inc. (SNC-Lavalin) for the exclusive use of Mount Polley Mining Corporation, who has been party to the development of the scope of work and understands its limitations. The methodology, findings, conclusions and recommendations in this report are based solely upon the scope of work and subject to the time and budgetary considerations described in the proposal and/or contract pursuant to which this report was issued. Any use, reliance on, or decision made by a third party based on this report is the sole responsibility of such third party. SNC-Lavalin accepts no liability or responsibility for any damages that may be suffered or incurred by any third party as a result of the use of, reliance on, or any decision made based on this report.

The findings, conclusions and recommendations in this report (i) have been developed in a manner consistent with the level of skill normally exercised by professionals currently practicing under similar conditions in the area, and (ii) reflect SNC-Lavalin's best judgment based on information available at the time of preparation of this report. No other warranties, either expressed or implied, are made as to the professional services provided under the terms of our original contract and included in this report. The findings and conclusions contained in this report are valid only as of the date of this report and may be based, in part, upon information provided by others. If any of the information is inaccurate, new information is discovered, site conditions change or applicable standards are amended, modifications to this report may be necessary.

Any soil and rock descriptions in this report and associated logs have been made with the intent of providing general information on the subsurface conditions of the site. This information should not be used as geotechnical data for any purpose unless specifically addressed in the text of this report. Groundwater conditions described in this report refer only to those observed at the location and time of observation noted in the report.

This report must be read as a whole, as sections taken out of context may be misleading. If discrepancies occur between the preliminary (draft) and final version of this report, it is the final version that takes precedence. Nothing in this report is intended to constitute or provide a legal opinion.

The contents of this report are confidential and proprietary. Other than by Mount Polley Mining Corporation, copying or distribution of this report or use of or reliance on the information contained herein, in whole or in part, is not permitted without the express written permission of Mount Polley Mining Corporation.

APPENDIX A

Maps of the terrestrial area affected by the debris flow and the locations of the reaches used in the analysis

LEGEND

- Terrestrial Affected Area
- Creek
- Lake

APPENDIX C

Cross-sections and photographs of the pre-event channel in the reaches from the Minnow (2007) report

REF No: REV: 0	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:
621717-HIA-C001	**HC-R1a Upper Hazeltine Creek**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**

SNC • LAVALIN

Area Overview

The uppermost reach HC-R1 was 445 m in length and displayed riffle-pool morphology. Banks were composed of fine grained material and stabilized by dense vegetation.

Hazeltine Creek Photographs (January 20, 2007)

Downstream view characteristically unconfined channel conditions at HC-R1. Substrate at such areas was typically fine gravel to sand.

Upstream view of channel at HC-R1 illustrating low gradient and densely vegetated riparian zone. 'Run' habitat was the dominant morphology type.

Area Overview

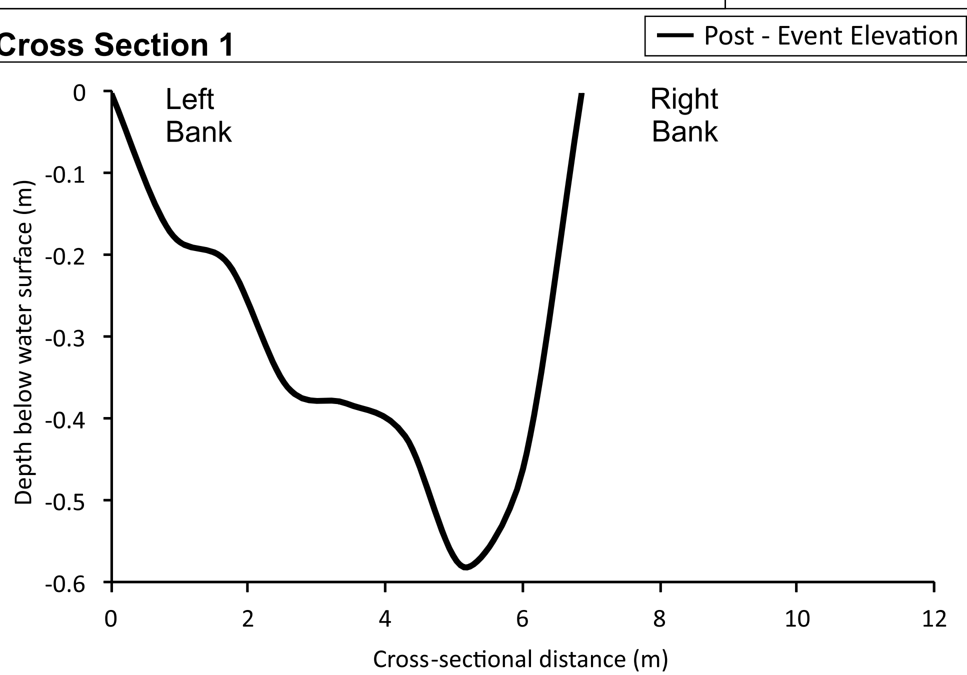
HC-R3 was located downstream of a beaver ponded area. This reach displayed riffle-pool morphology, and was characterized by low gradient and side-channels.

Hazeltine Creek Photographs (January 20, 2007)

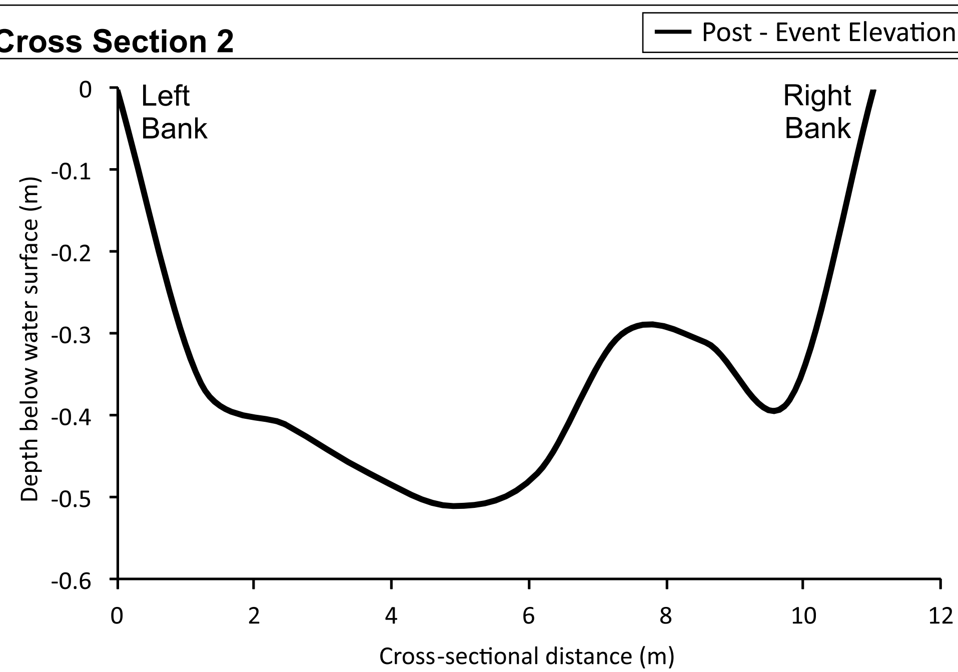
Habitat at Reach HC-R3 was characterized by low gradient, run morphology with predominantly sand substrate.

Side channels and the occurrence of unstable banks were more prevalent at Reach HC-R3, likely as a result of multiply overflow points across a beaver dam that marked the upper boundary of the reach.

Cross Section 1



Cross Section 2



REF No: 621717-HIA-C004	REV: **0**	REACH: **HC-R4 Upper Hazeltine Creek**	CLIENT NAME: **Mount Polley Mining Corporation**	PROJECT LOCATION: **Mount Polley Mine, Likely, BC**	DATE: **2015/04/01**	SNC • LAVALIN

Area Overview

Reach HC-R4 began downstream of the Gavin Lake road bridge. Surface water flow was variable and hyporheic flow was suspected. Bank stability was low in this reach, and undercutting was observed.

Hazeltine Creek Photographs (January 20, 2007)

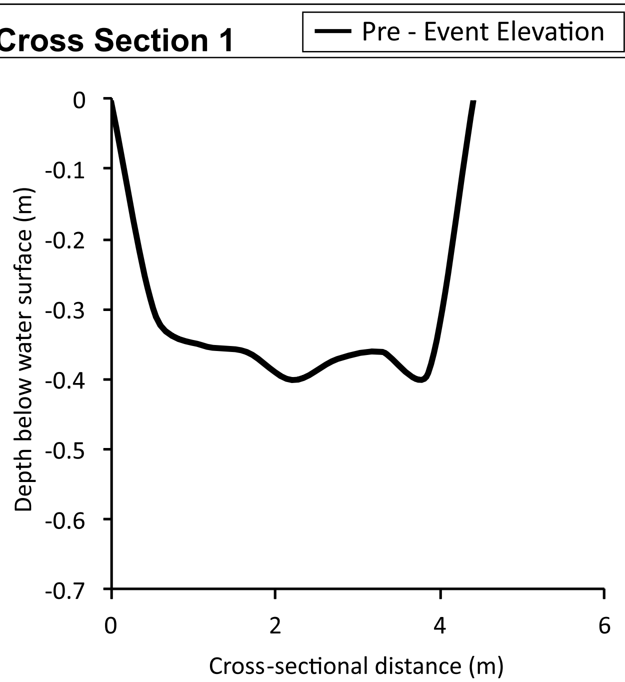
Upstream view towards the Mount Polley Mine water gauge station on Hazeltine Creek at Gavin Lake Road. This is the upper boundary of Reach HC-R4.

Example of an undercut bank in HC-R4. Although undercut banks were common through this reach, overall bank stability was generally considered moderate.

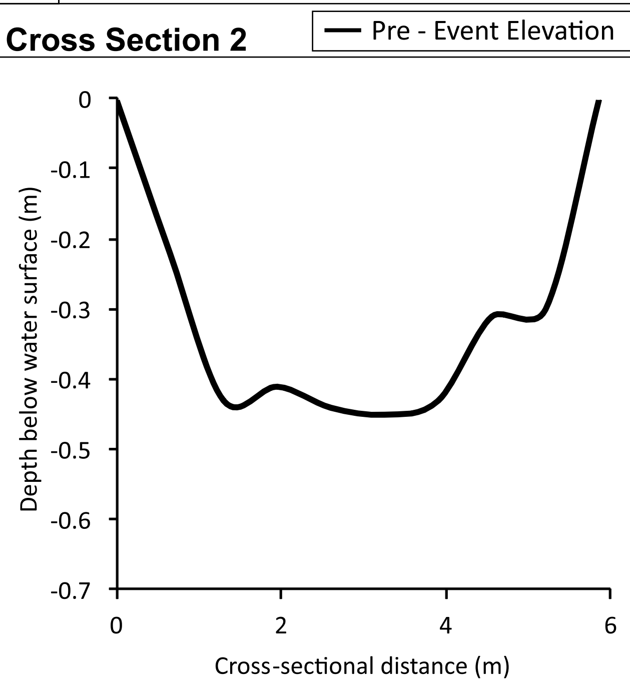
Upstream view of general stream conditions through HC-R4. Low water levels at the time resulted in higher stream-bed exposure. Substrate consisted of cobble-gravel.

Although Edney Creek was the only surface water tributary feeding Hazeltine Creek, groundwater seeps containing high iron content were occasionally observed. This small seep is an example.

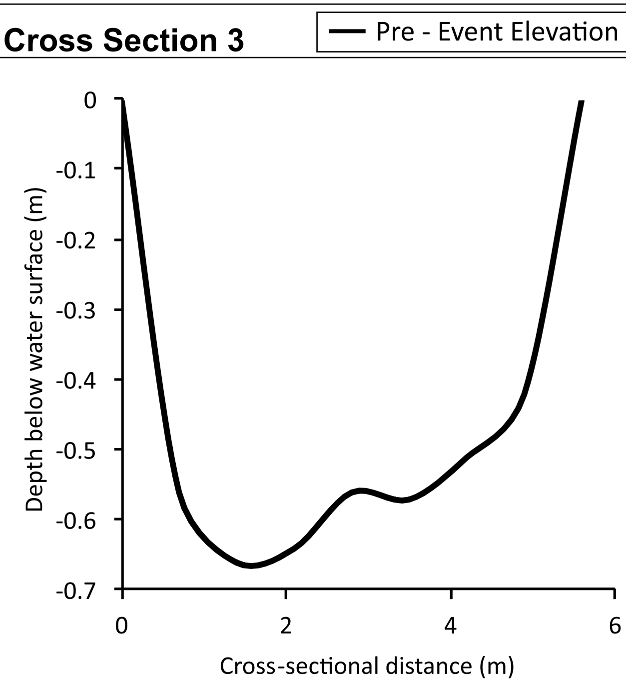
Cross Section 1



Cross Section 2



Cross Section 3



REF No: REV: 0	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC • LAVALIN
621717-HIA-C005	**HC-R5 Upper Hazeltine Creek**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	

Area Overview

HC-R5 displayed riffle-pool morphology and higher gradient (3.7 %) relative to upstream reaches. Banks were considered moderately stable, and some valley sides had slumped into the channel.

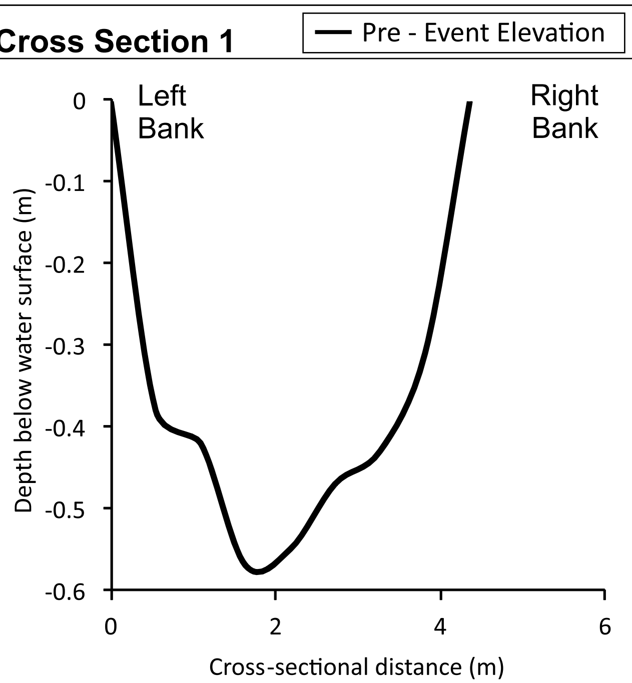
Hazeltine Creek Photographs (January 20, 2007)

Downstream view of typical channel through HC-R5. This reach was characterized by a clear gradient shift (3.7 %) relative to upstream areas.

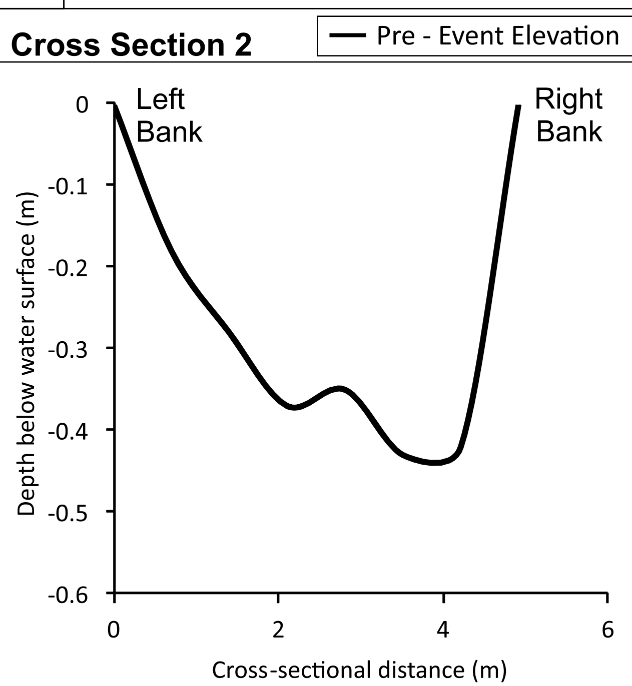
Slumping valley walls such as the one illustrated above were observed at two locations along Hazeltine Creek, both of which were within HC-R5.

Upstream view of an approximately 1.2 m high cascade found in the lower portion of Reach HC-R5. This cascade likely acted as a barrier to upstream fish migration, particularly during low flow periods.

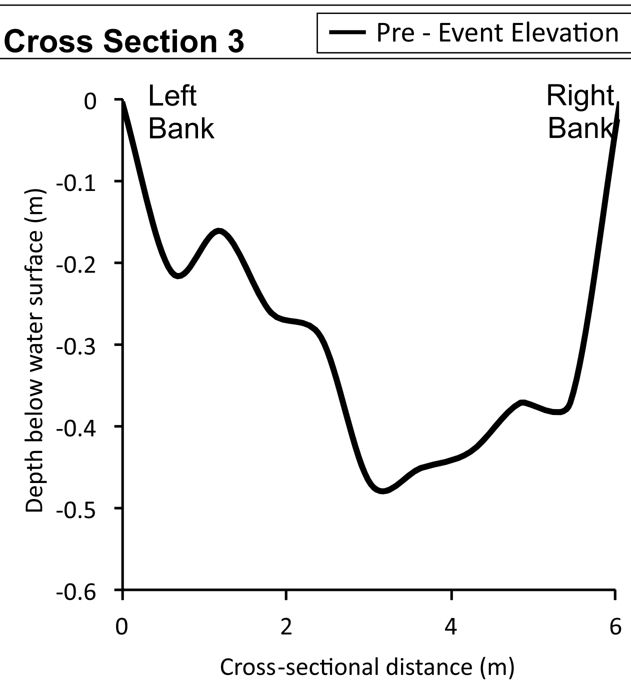
Cross Section 1



Cross Section 2



Cross Section 3



REF No: REV: **0**	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:
621717-HIA-C006	**HC-R6 Hazeltine Creek Canyon**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**

SNC • LAVALIN

Area Overview

Hazeltine Creek entered a 1,510 m long canyons at HC-R6. The channel was lined with bedrock, boulders and cobbles, and displayed step-pool morphology. This reach was extremely stable.

Hazeltine Creek Photographs (January 20, 2007)

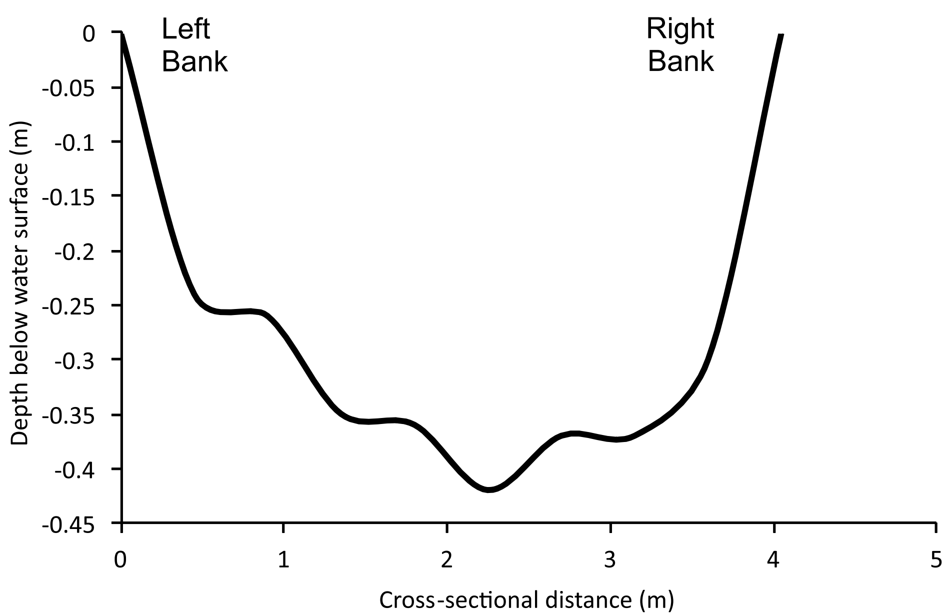
HC-R6 represented that portion of Hazeltine Creek which passed through a steep-walled gorge. Bank stability was considered good at HC-R6 as a result of a high proportion of bedrock/cobble in the banks.

In-stream barriers, such as this large debris jam, were common through HC-R6, likely preventing upstream fish migration at all but the highest flows.

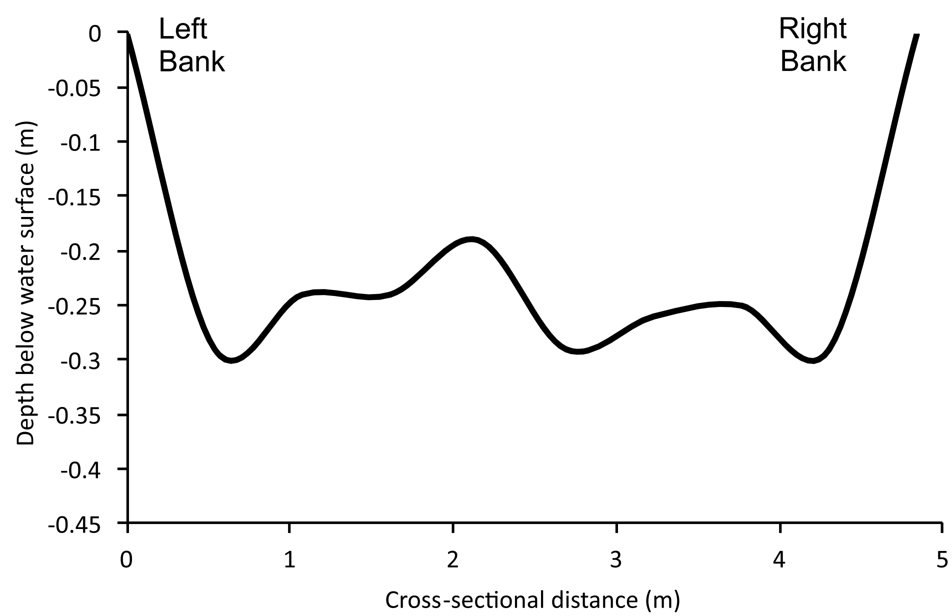
Step-pools with cobble substrate characterized HC-R6 habitat. Mean gradient through this reach was approximately 7%.

In-stream barriers at HC-R6 also included areas of aggraded cobble over log debris, which resulted in short sections of hyporheic flow.

Cross Section 2



Cross Section 3



REF No: 621717-HIA-C007	REV: **0**	REACH: **HC-R7 Lower Hazeltine Creek**	CLIENT NAME: **Mount Polley Mining Corporation**	PROJECT LOCATION: **Mount Polley Mine, Likely, BC**	DATE: **2015/04/01**	SNC • LAVALIN

Area Overview

HC-R7 was the first reach of Lower Hazeltine Creek, extending from the mouth of the canyon to just below the ditch road. The channel displayed riffle-pool morphology with stable banks.

Hazeltine Creek Photographs (January 20, 2007)

Downstream view of typical Reach HC-R7 habitat. Moderate gradient, riffle-run stream morphology and cobble substrate were key features of this reach.

Cross Section 1

621717-HIA-C008	**HC-R8 Lower Hazeltine Creek**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	SNC · LAVALIN

Area Overview

HC-R8 extended 555 m downstream of HC-R7 to the confluence with Edney Creek. The reach was characterized by relatively lower gradient, smaller substrate grain size, and lower bank stability.

Hazeltine Creek Photographs (January 20, 2007)

Downstream view of Reach HC-R8 in its upper portion. Low gradient run habitat with gravel substrate and dense overhanging vegetation were dominant features of this reach.

Downstream view of Reach HC-R8 in its lower portion. At this area, the creek flows through cedar lowland habitat and some bank undercutting occurs. Stream flow increases substantially at HC-R8 relative to upstream areas.

Cross Section 1

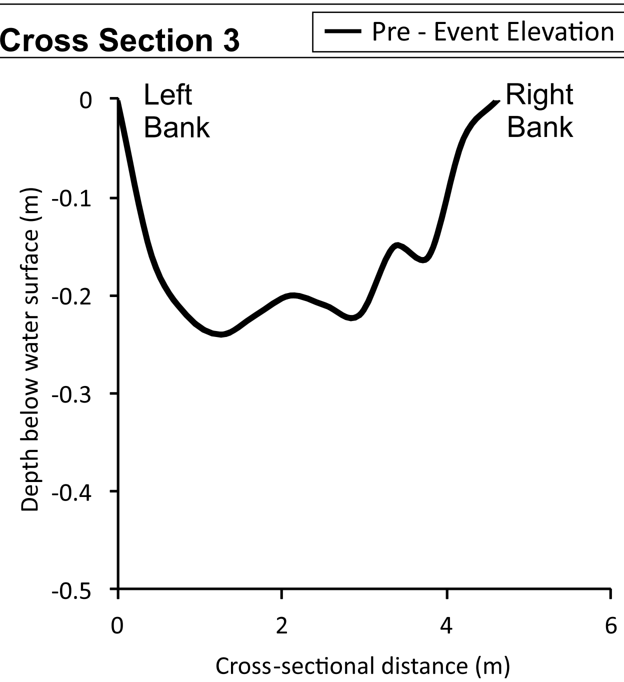
Cross Section 3



REF No: REV: 0	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC • LAVALIN
621717-HIA-C009	**HC-R9 Lower Hazeltine Creek**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	

Area Overview

HC-R9 is the final reach of Hazeltine Creek, extending from the confluence with Edney Creek to Quesnel Lake. This reach displayed riffle-pool morphology and relatively stable banks.

Hazeltine Creek Photographs (January 20, 2007)

Upstream view of HC-R9 in its upper portion. Low gradient run habitat and cobble-grael substrate characterized this reach.

Hazeltine Creek approximately 400 m upstream of Quesnel Lake. Fish habitat included some pool and woody debris in lower Hazeltine Creek, although the relative amount of functional habitat was considered low.

Upstream view of HC-R9 approximately 385 m upstream of the outlet of Hazeltine Creek. This is the location of water sample Station W11.

Riffle habitat in lower Hazeltine Creek was generally shallow (< 10 cm deep) and likely to restrict upstream movement of large fish.

APPENDIX H

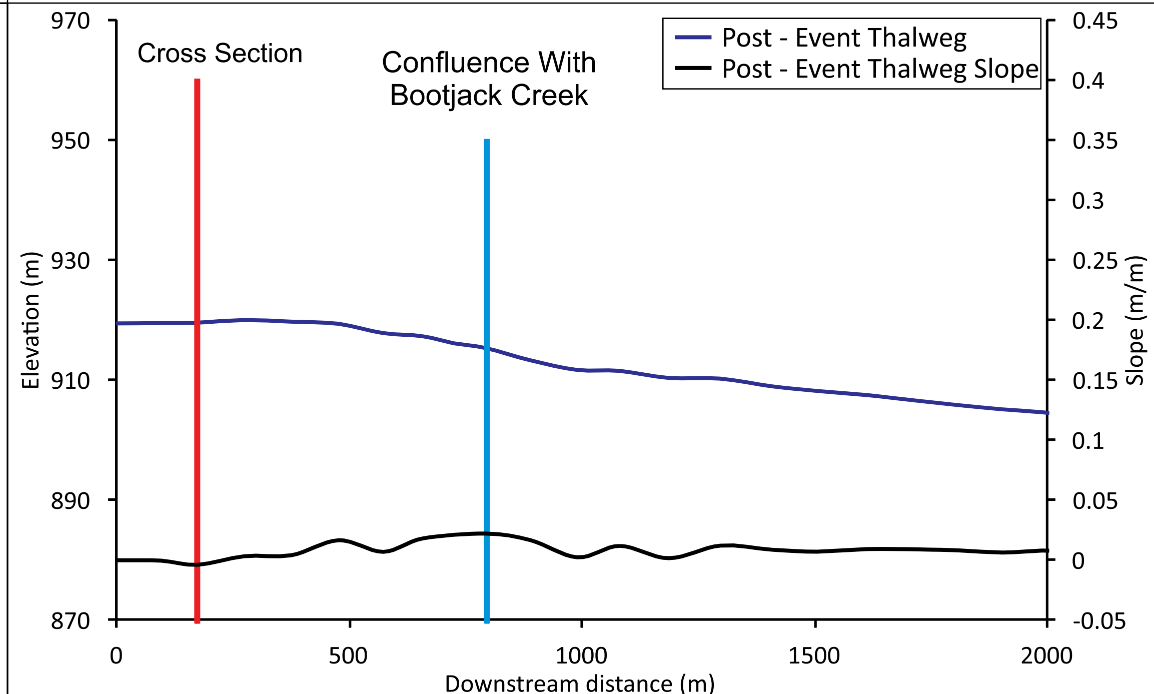
Cross-sections and photographs of the post-event channel in the reaches modified from the Minnow (2007 C) report

REF No: 621717-HIA-H001	REV: **0**	AREA: **Hazeltine Creek Plug**	REACH: **HC-R0**	CLIENT NAME: **Mount Polley Mining Corporation**	PROJECT LOCATION: **Mount Polley Mine, Likely, BC**	DATE: **2015/04/01**	SNC·LAVALIN

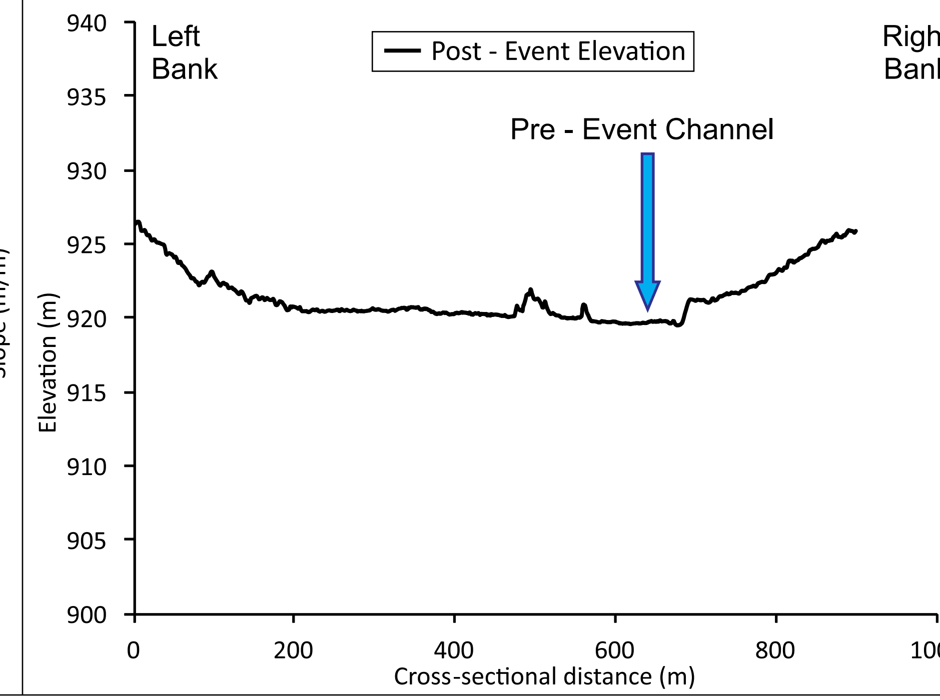
Area Overview

The Plug extends 1,750 m from the south end of Polley Lake. The area is dominated by debris flow deposits composed of tailings, native material and embankment material that span up to 350 m laterally.

Long Profile



Cross Section



Typical Deposits and Surficial Material

Deposition within the plug area looking upstream towards Polley Lake (September 22, 2014).

Aerial view looking west toward the Mount Polley Mine Site at the Polley Lake post-event shoreline (September 22, 2014).

View looking downstream from Polley Lake. Fine grained tailings have been deposited across the wide floodplain to form the Plug.

Aerial view looking east across the Polley Lake post-event shoreline (September 22, 2014).

Key Features and Identified Impacts

View looking toward Polley Lake. The event resulted in the removal of all but a few trees and other vegetation along the path of flow.

The plug contains debris flow deposits from the event, which includes a mixture of tailings, TSF embankment material, and eroded native soils and vegetation.

Deposition within the plug area looking towads Polley Lake, people for scale (September 22, 2014).

Nineteenth century diversion ditch containing water from Polley Lake looking downstream (September 22, 2014).

Eastern edge of plug area with nineteenth century diversion ditch (September 22, 2014).

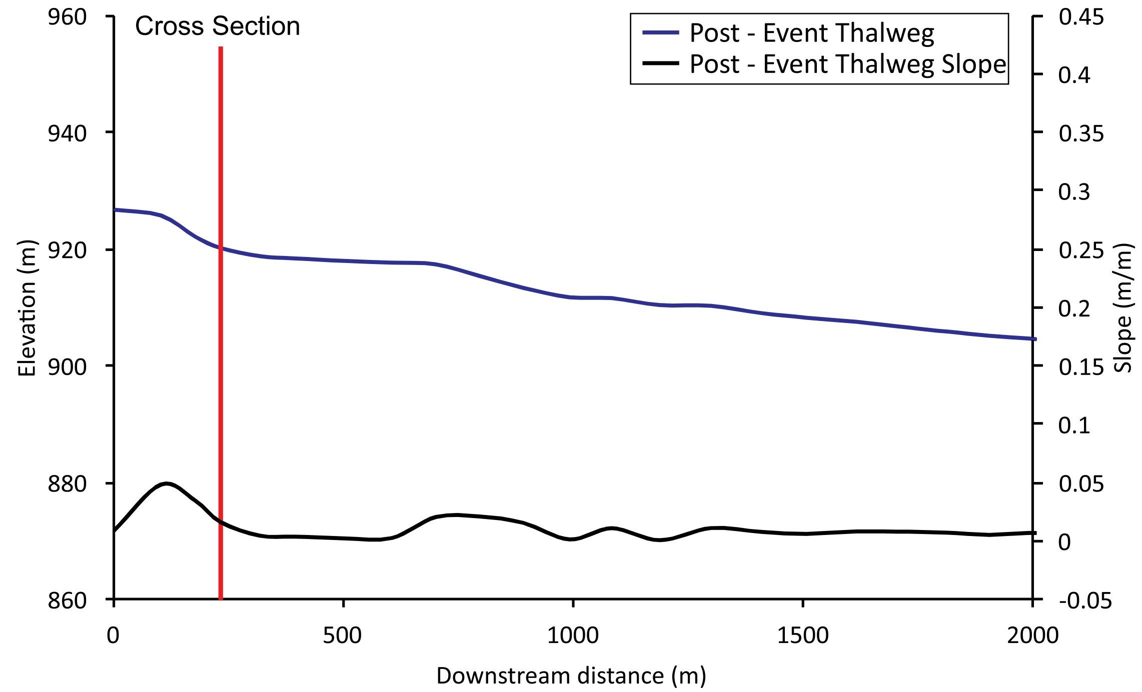
The maximum vertical extent of the debris flow event is shown by scarring and mud lines present on standing vegetation within the path of flow.

REF No: 621717-HIA-H002	REV: 0	AREA: Upper Hazeltine Creek	REACH: HC-R0a	CLIENT NAME: Mount Polley Mining Corporation	PROJECT LOCATION: Mount Polley Mine, Likely, BC	DATE: 2015/04/01	SNC·LAVALIN

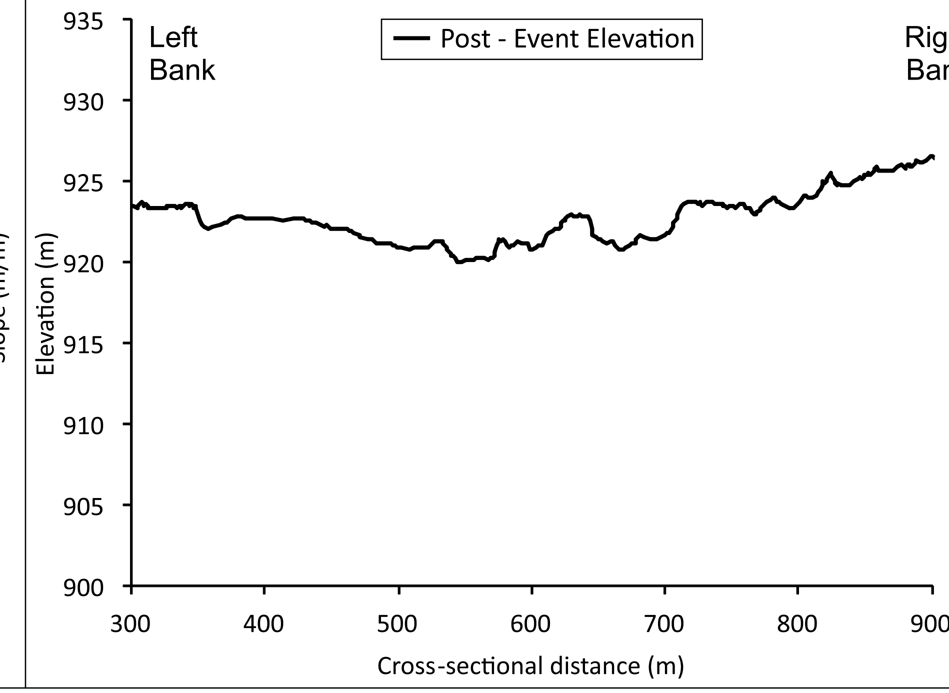
Area Overview

Reach HC-R0a is located directly downstream of the TSF breach and extends downslope to Hazeltine Creek.

Long Profile



Cross Section



Typical Deposits and Surficial Material

Aerial view of the TSF breach looking west. (September 05 2014)

Aerial view of the affected site directly downstream of the breach location. The debris flow removed vegetation in its path (September 5, 2014).

A vertical exposure of embankment material deposited by the event. A thin crust of fine-grained tailings is visible on the surface of the deposit (September 23, 2014).

A block of intact material deposited by the event (September 23, 2014).

Key Features and Identified Impacts

Downstream view towards the confluence of the debris flow and the pre-event Hazeltine Creek channel (September 23, 2014).

Upstream view toward the TSF. Flow from the TSF is incising into the native material and debris flow deposit (September 23, 2014).

Dessication cracks and blocks of transported material are visible on the hummocky post-event surface (September 23, 2014).

Deposition within the HC-R0a area looking downstream from the breach (September 22, 2014).

Upstream view toward the TSF. A small stand of trees remains after the event (September 23, 2014).

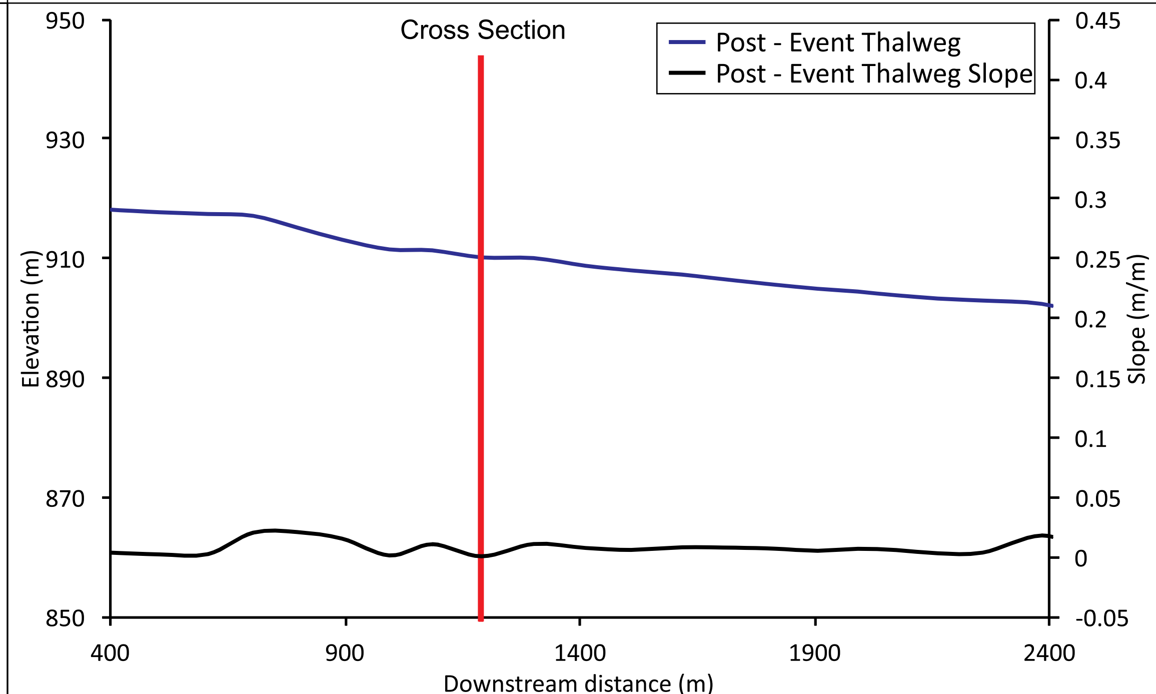
Northern edge of trees showing deposition within HC-R0a (September 22, 2014).

REF No: REV: **0**	AREA:	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC • LAVALIN
621717-HIA-H003	**Upper Hazeltine Creek**	**HC-R0**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	

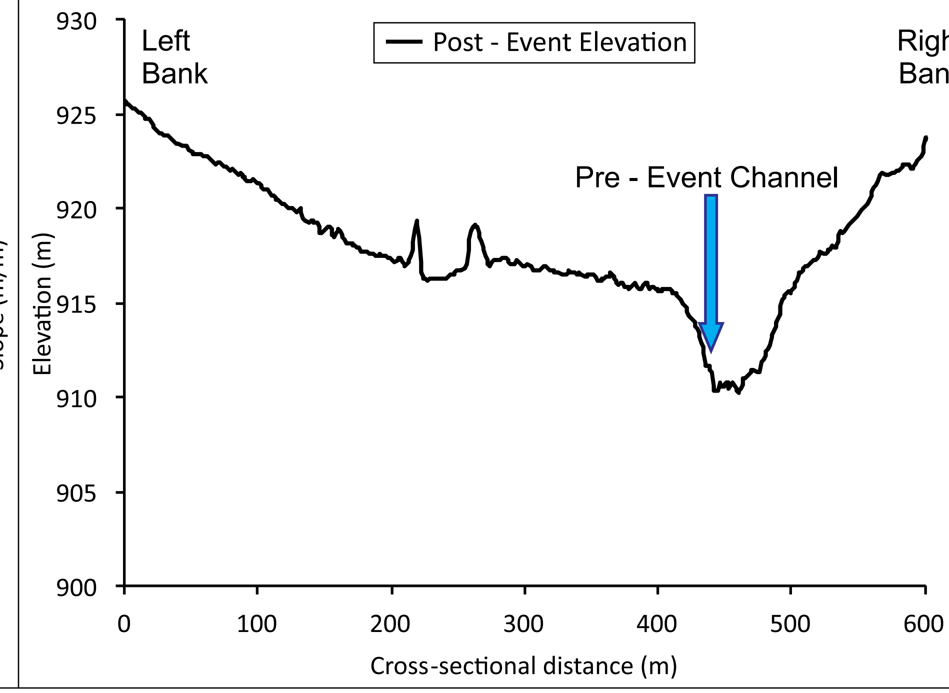
Area Overview

Reach HC-R0b extends downstream of the confluence between the debris flow and Hazeltine Creek. The affected channel contains three tree islands where the event divided into two channels.

Long Profile



Cross Section



Typical Deposits and Surficial Material

View of the right bank, where the steep banks are failing due to lateral erosion (September 23, 2014).

Knickpoints such as this are common features in this reach (September 23, 2014).

View of a dry side-channel eroded into native fluvial/glacio-fluvial material (September 23, 2014).

An exposed fluvial/glacio-fluvial deposit with a thin coating of tailings on the left bank (September 23, 2014).

Key Features and Identified Impacts

Upstream view of a knickpoint incised into native material (September 23, 2014).

Downstream view of a series of knickpoints (September 23, 2014).

A sequence of cutbanks lining the left bank indicate the pattern of flow recession following the event.

Downstream view including a wooden platform that was exposed following the event (September 23, 2014).

View of a tree island with several felled trees (left of photo). Photo facing downstream (September 23, 2014).

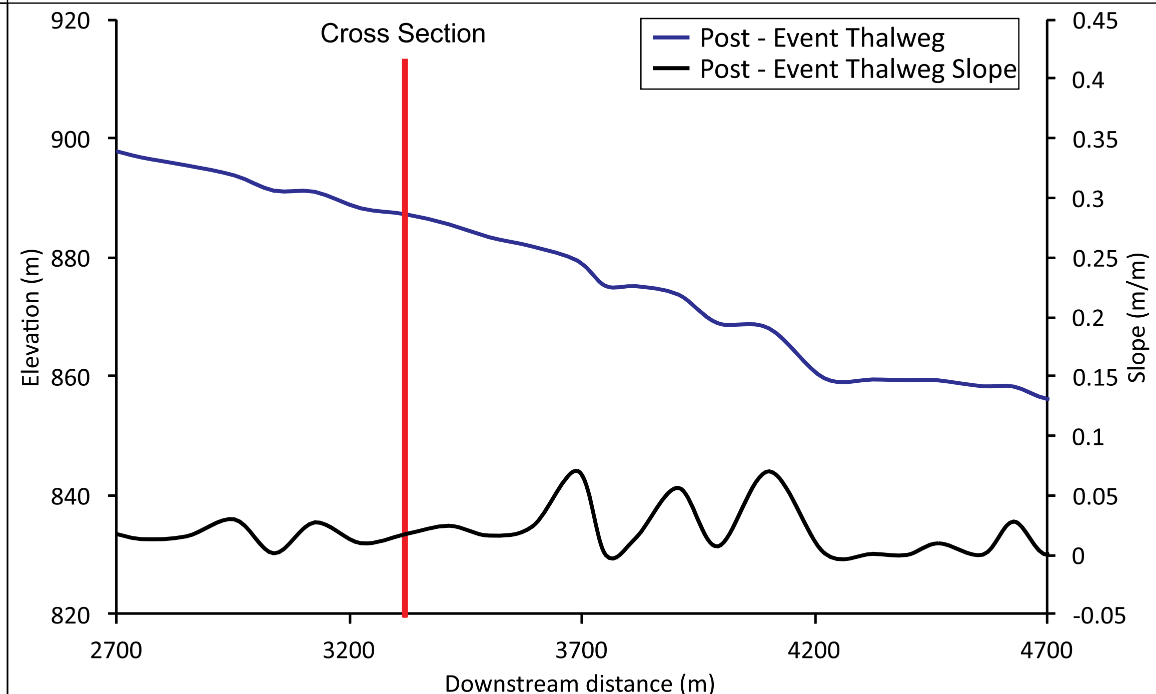
Cutbank exposed on the left bank. Fine grained tailings sands have been deposited at the edge of the channel. (September 23, 2014).

REF No: REV: 0	AREA:	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC·LAVALIN
621717-HIA-H004	**Upper Hazeltine Creek**	**HC-R4a**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	

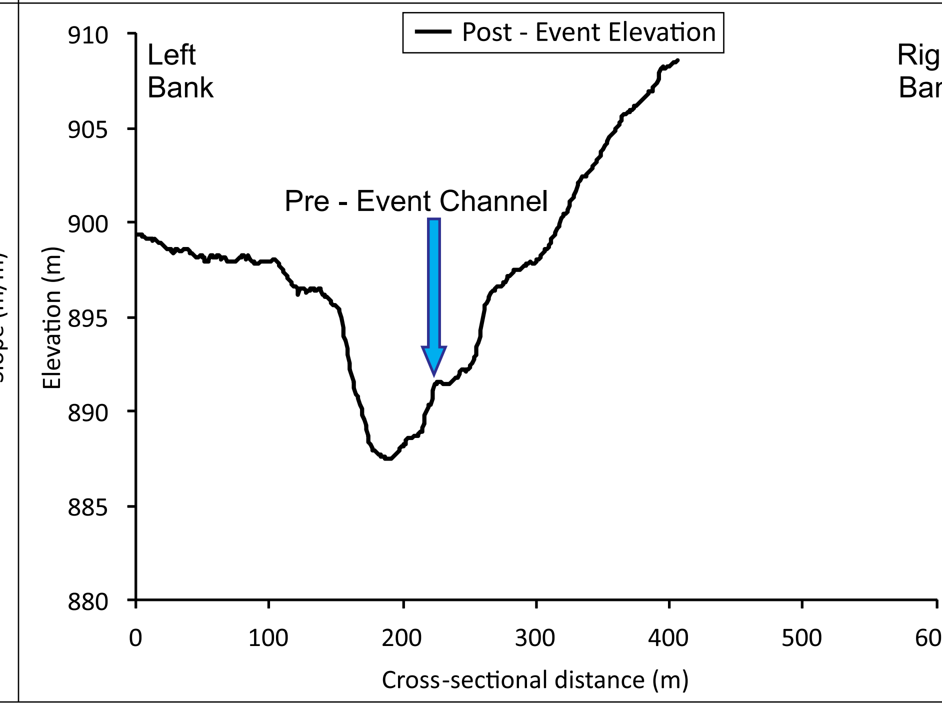
Area Overview

HC-R4a is located between the Gavin Lake Road bridge and the upstream most large knick-point in HC-R4

Long Profile



Cross Section



Typical Deposits and Surficial Material

Upstream view towards the right bank of Hazeltine Creek. The channel is incising into glacial till (September 24, 2014).

The channel flows in an irregular meander through the bed material (September 24, 2014).

Large woody debris deposits on the upper banks of the channel (September 24, 2014).

Upstream view of a thin layer of fine-grained tailings has been deposited on the Hazeltine Creek floodplain (September 24, 2014).

Key Features and Identified Impacts

Downstream view of the main channel and an incising side channel (September 24, 2014).

Upstream view of the post-event channel incising into the bed material, resulting in steep, occasionally undercut banks.

The banks of this reach are marked by large piles of woody debris transported by the event (September 24, 2014).

The washed out Gavin Lake Road bridge has been deposited on the upper left bank of the channel (September 24, 2014).

View upstream of a knickpoint incised into glacial till (September 24, 2014).

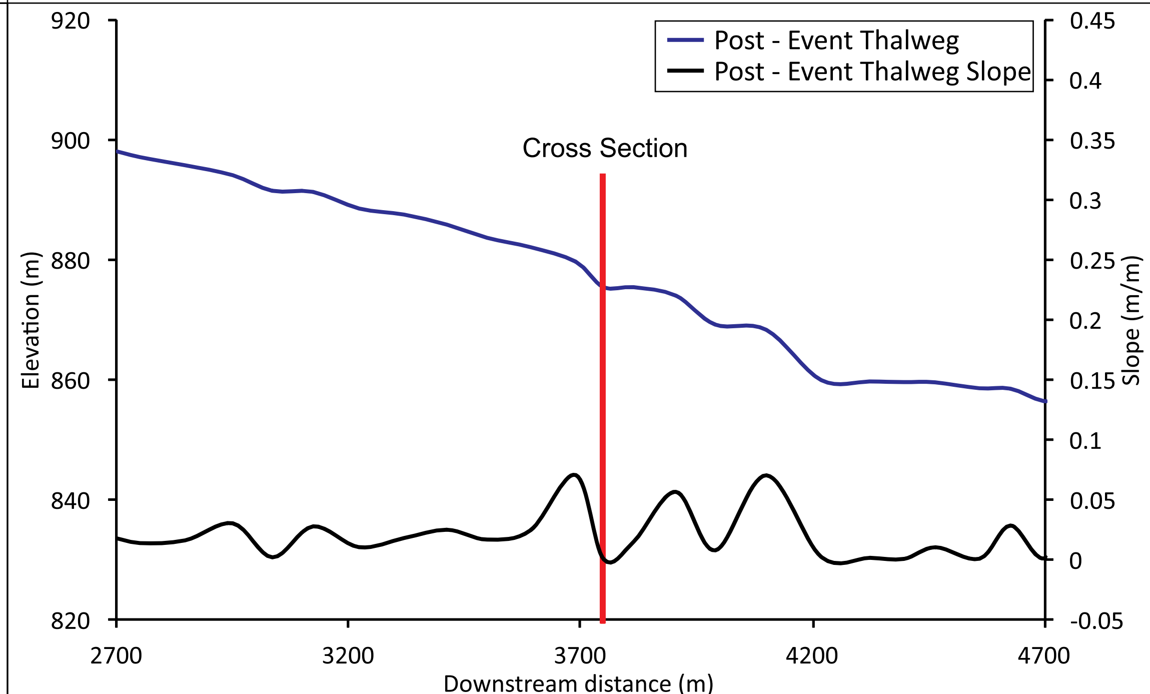
The maximum vertical extent of the event is shown by scarring and mud lines present on standing vegetation. Person for scale (September 24, 2014).

REF No: REV: 0	AREA:	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC • LAVALIN
621717-HIA-H005	**Upper Hazeltine Creek**	**HC-R4b**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	

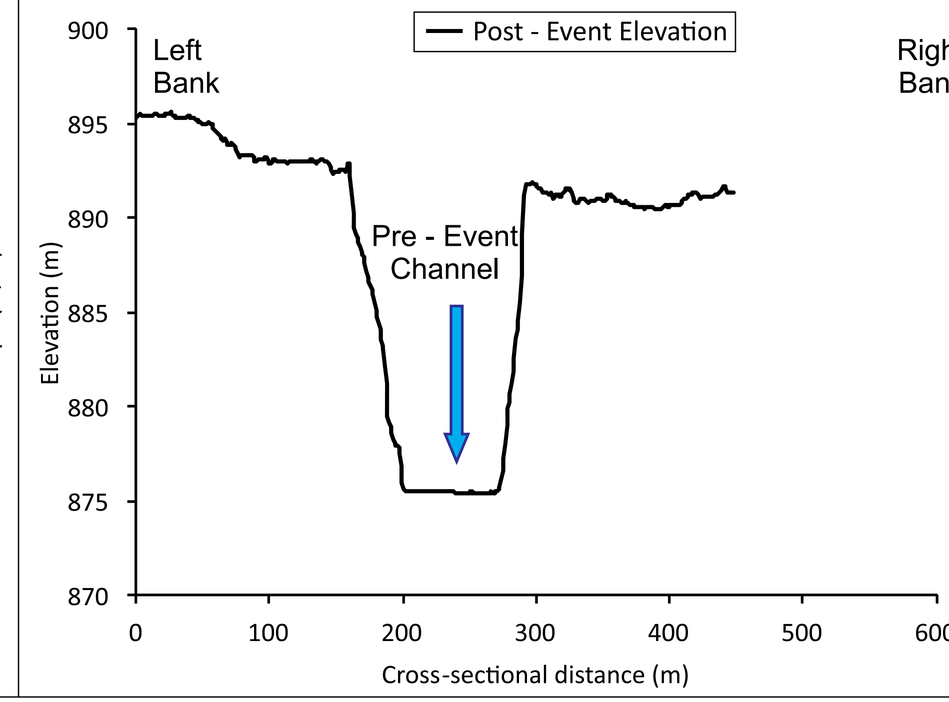
Area Overview

HC-R4b contains large knick-points and is located between the upstream most large knick-point and HC-R5a.

Long Profile



Cross Section



Typical Deposits and Surficial Material

Downstream view of the entrenched channel iincising into fine-grained native material (September 24,2014

View of the left bank of Hazeltine Creek. Large blocks of fine-grained native bank material have calved into the channel.

View of the downstream extent of a deeply entrenched section. Deposition has occurred where the channel widens.

Looking downstream, the channel widens, and depositional bars have formed (September 24, 2014).

Key Features and Identified Impacts

Large tension cracks form at the downstream extent of the lacustrine deposit.

Tension cracks indicate a high potential for failure at the downstream extent of the entrenched section.

Failed sediment and vegetation along the right bank due to lateral bank erosion (September 24, 2014).

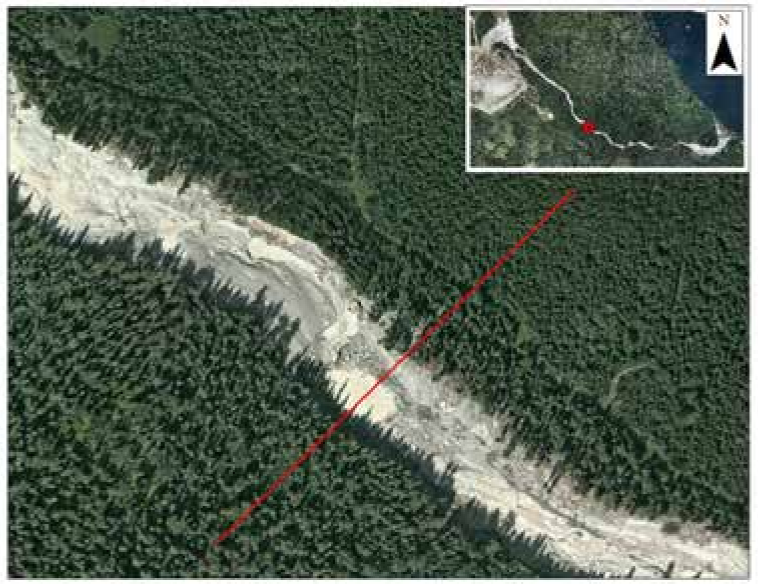
Channel incision into the thick lacustrine/glaciolacustrine deposit has led to rapid lateral erosion with calving blocks.

Downstream view of the channel widening and displaying a braided pattern (September 24, 2014)

Downstream view of tension cracks in a sandy tailings deposit (September 24, 2014).

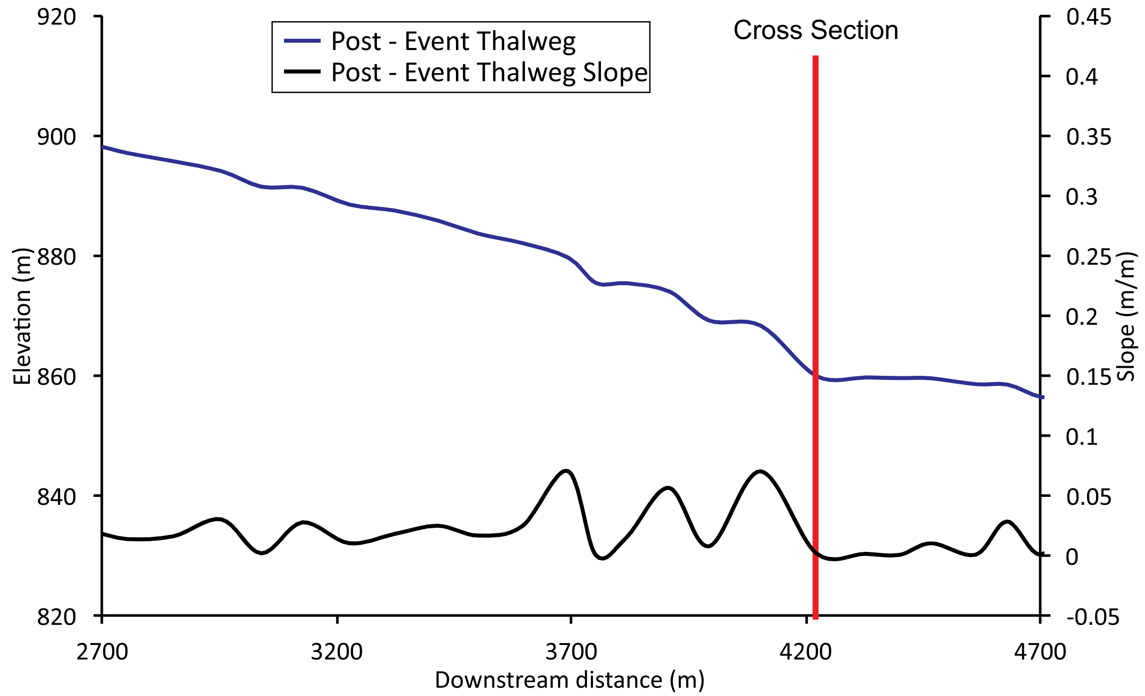
REF No: REV: **0**	AREA:	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC • LAVALIN
621717-HIA-H006	**Upper Hazeltine Creek**	**HC-R4 b**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	

Area Overview

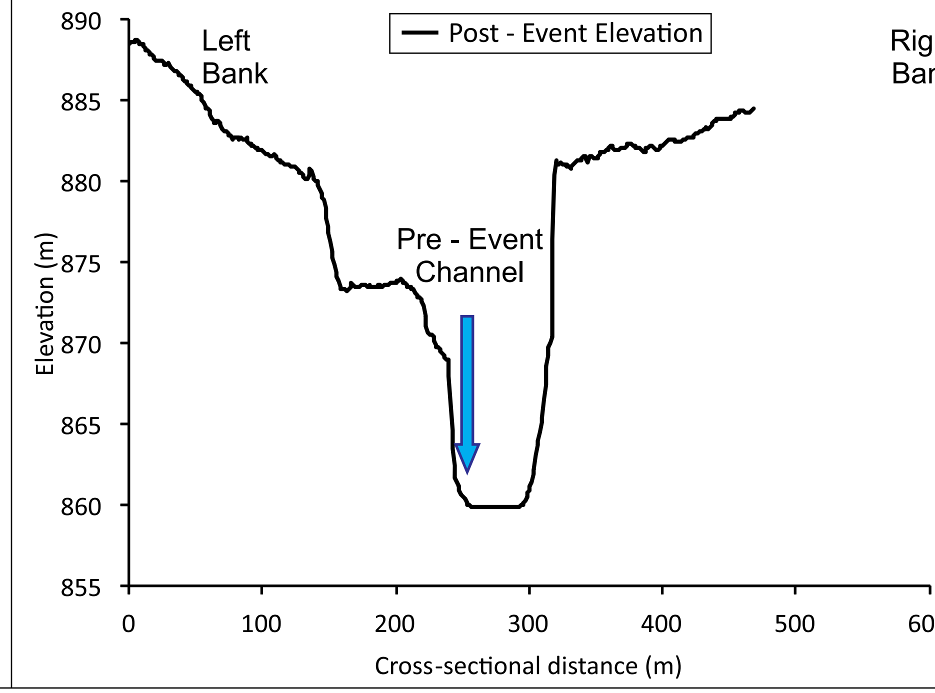


HC-R4b contains large knick-points and is located between the upstream most large knick-point and HC-R5a.

Long Profile



Cross Section



Typical Deposits and Surficial Material

Entrenched channel upstream of a knickpoint. Calved blocks and debris are present in the Hazeltine Creek channel (September 25, 2014).

A sandy tailings deposit overlying native fluvial and lacustrine layers (September 25, 2014).

An abandoned entrenched side channel that was incised during the event. (September 25, 2014)

View downstream of cobble-sized material deposited in the channel, shovel for scale (September 25, 2014).

Key Features and Identified Impacts

View upstream toward the knickpoint. The elevation of the banks decreased abruptly by as much as 5 m (September 25, 2014).

View upstream towards the knickpoint, where the emerging channel displays a braided pattern (September 25, 2014).

Aerial view of the right cutbank (September 5, 2014).

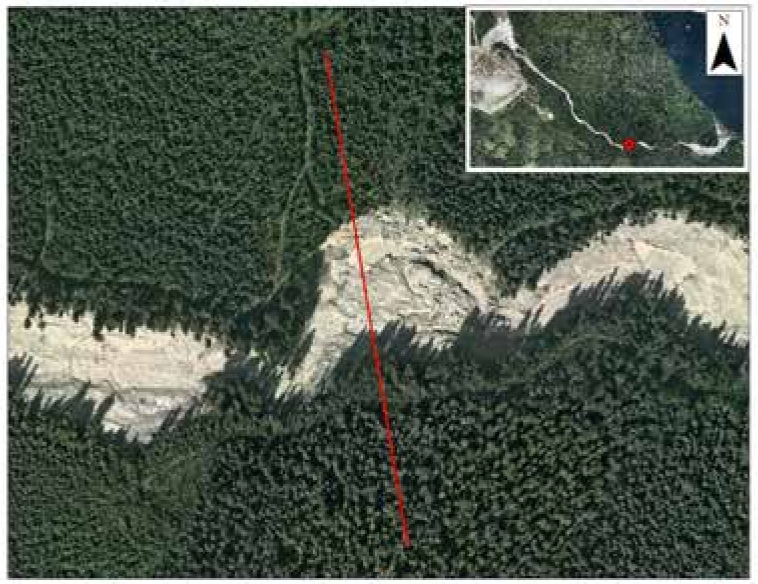
View of the right cutbank. Calved blocks and large woody debris has fallen into the channel (September 25, 2014).

A large boulder in an entrenched section of the channel. The boulder is likely sourced from native till, and deposited as the event flows were receding (September 25, 2014).

Aerial view looking upstream towards the knickpoint. (September 5, 2014).

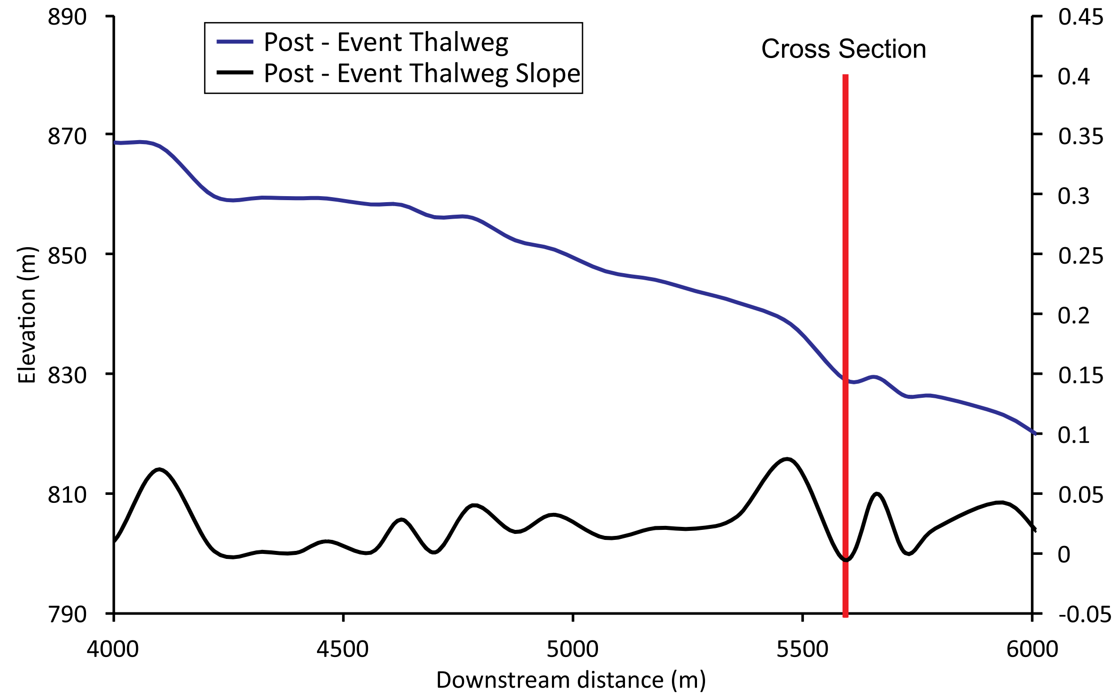
REF No: REV: **0**	AREA:	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC·LAVALIN
621717-HIA-H007	**Upper Hazeltine Creek**	**HC-R5b**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	

Area Overview

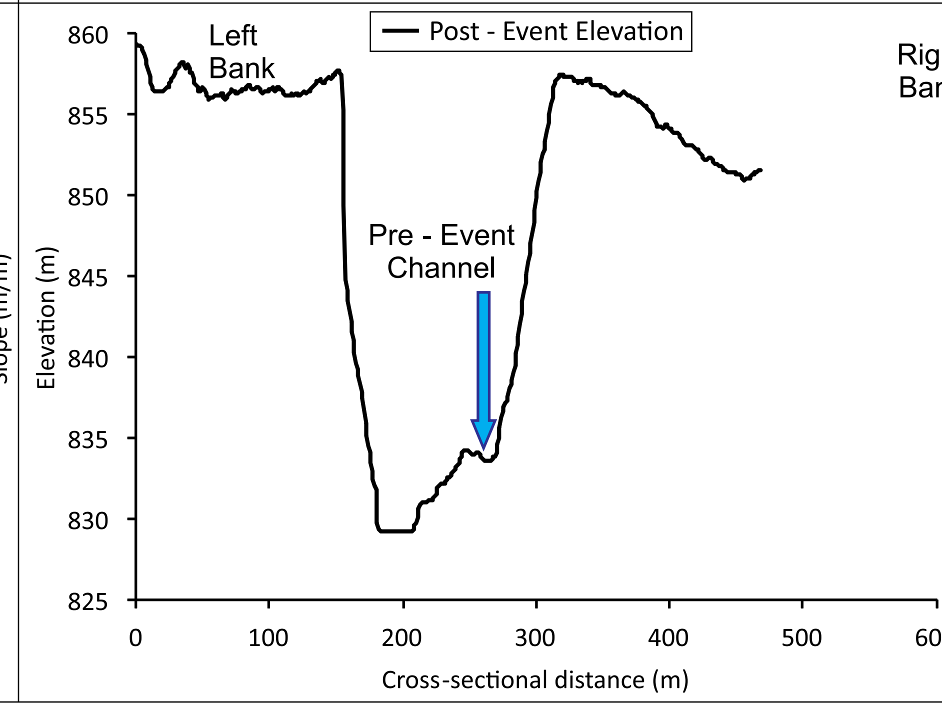


HC-R5b is located in a wide and laterally unstable section of the valley between the downstream end of HC-R5a and the entrance to the Hazeltine Creek Canyon (HC-R6).

Long Profile



Cross Section



Typical Deposits and Surficial Material

Downstream view of the steep failed wall on the left side of the valley (September 26, 2014).

Upstream view towards the failed left valley wall. Large calved blocks are present in the channel (September 26, 2014).

Downstream view where blocks of bedrock and bank material are visible in channel (September 26, 2014).

View of the channel from the top of the left bank. Channel bed is scoured to bedrock (September 26, 2014).

Key Features and Identified Impacts

Downstream view of the channel entering a small bedrock canyon at the upstream extent of the reach (September 26, 2014).

The post-event Hazeltine creek splits into two channels at the upstream extent of this reach, and converges downstream as flow leaves the reach (September 26, 2014).

View downstream, large boulder-sized blocks of cohesive material are present in the channel (September 26, 2014).

Exposed bedrock in the bed of the channel has limited the amount of incision in this reach, but likely increased lateral bank erosion.

Tension cracks at the top of the left bank indicate a high potential for bank failure (September 26, 2014).

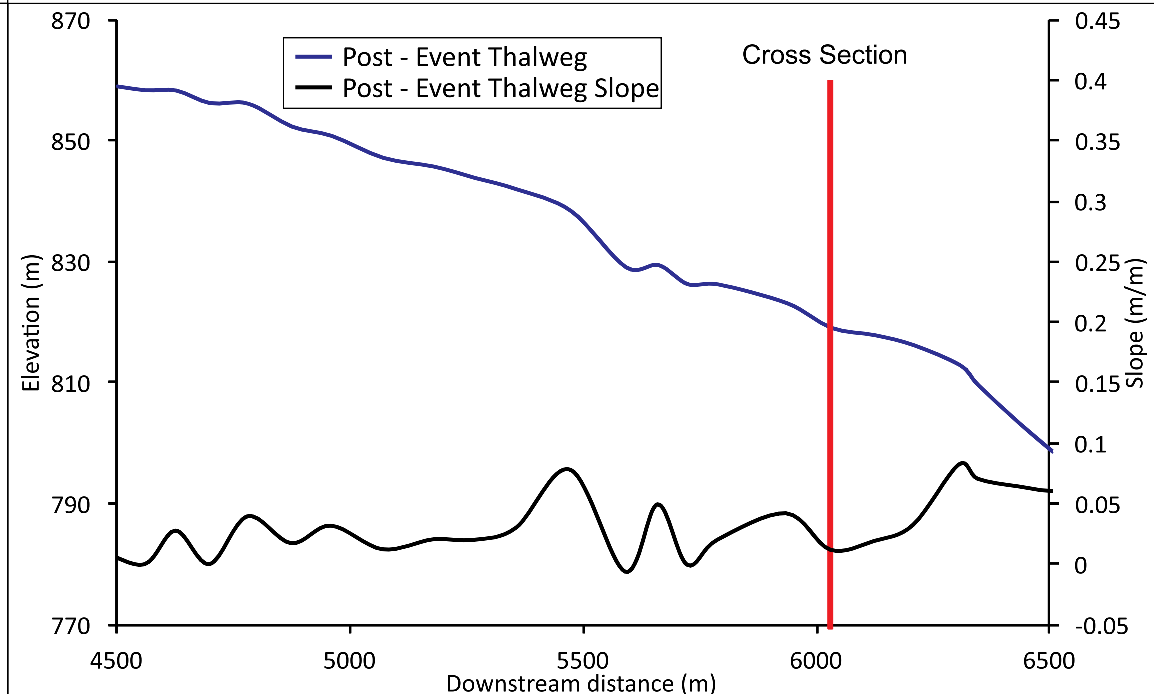
View of the right bank at the downstream extent of the reach (September 26, 2014).

REF No: 621717-HIA-H008	REV: 0	AREA: Upper Hazeltine Creek	REACH: HC-R5b	CLIENT NAME: Mount Polley Mining Corporation	PROJECT LOCATION: Mount Polley Mine, Likely, BC	DATE: 2015/04/01	SNC·LAVALIN

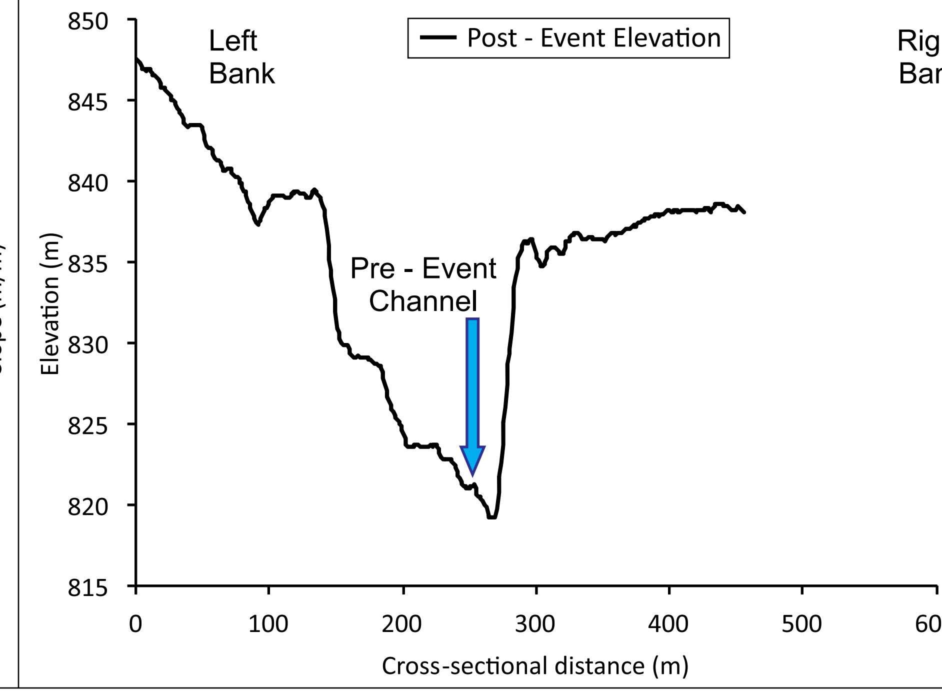
Area Overview

HC-R5b is located in a wide and laterally unstable section of the valley between the downstream end of HC-R5a and the entrance to the Hazeltine Creek Canyon (HC-R6).

Long Profile



Cross Section



Typical Deposits and Surficial Material

Downstream view of sandy tailings overlying fluvial deposits on the left bank (September 26, 2014).

Downstream view from an abandoned channel (September 26, 2014).

Exposed native fluvial material in an exposed section of the right bank (September 26, 2014).

A root mat overlying native fluvial sediments provides evidence of the pre-event ground surface on the left bank (September 26, 2014).

Key Features and Identified Impacts

Upstream view of a cutbank on the right side of the valley. Mud lines on trees indicates the upper vertical extent of the flow event.

Upstream view of a knickpoint characteristic of this reach (September 26, 2014).

View of the right bank. Boulder-sized blocks of cohesive material deposited on the bank, and mud lines on the trees provide evidence of the vertical extent of the event (September 26, 2014).

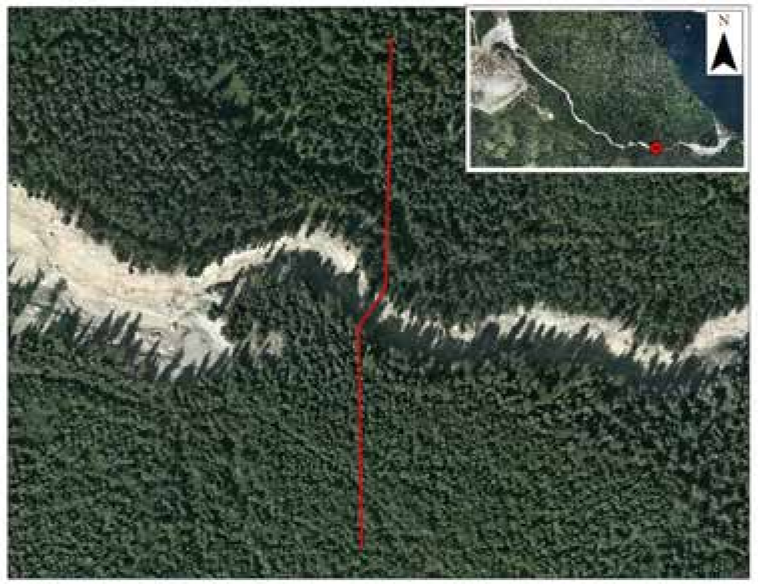
Example of an undercut bank observed in this reach. Undercut banks were common due to the soft underlying lacustrine deposits.

Eroded fluvial terraces on the left bank. Dense roots in the deposit suggest the terraces are near the pre-event ground surface (September 26, 2014).

Upstream view from the top of the left bank. Large cohesive blocks of material are visible on the surface (September 26, 2014).

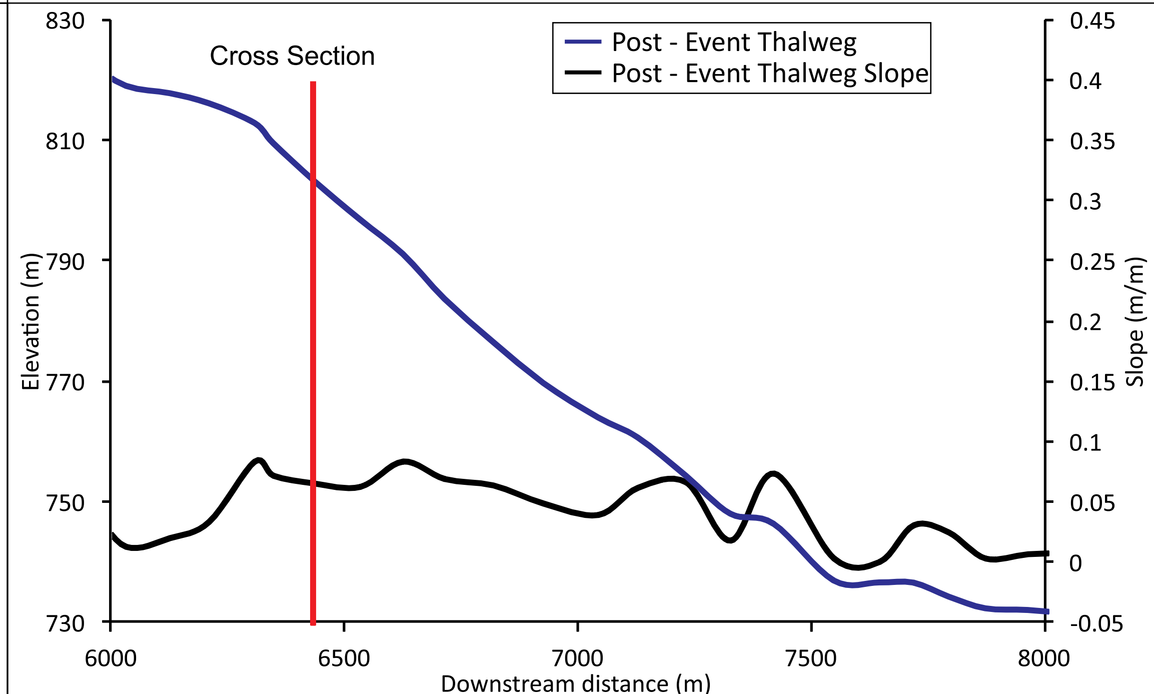
REF No: REV: 0	AREA:	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC • LAVALIN
621717-HIA-H009	Hazeltine Creek Canyon	HC-R6	Mount Polley Mining Corporation	Mount Polley Mine, Likely, BC	2015/04/01	

Area Overview

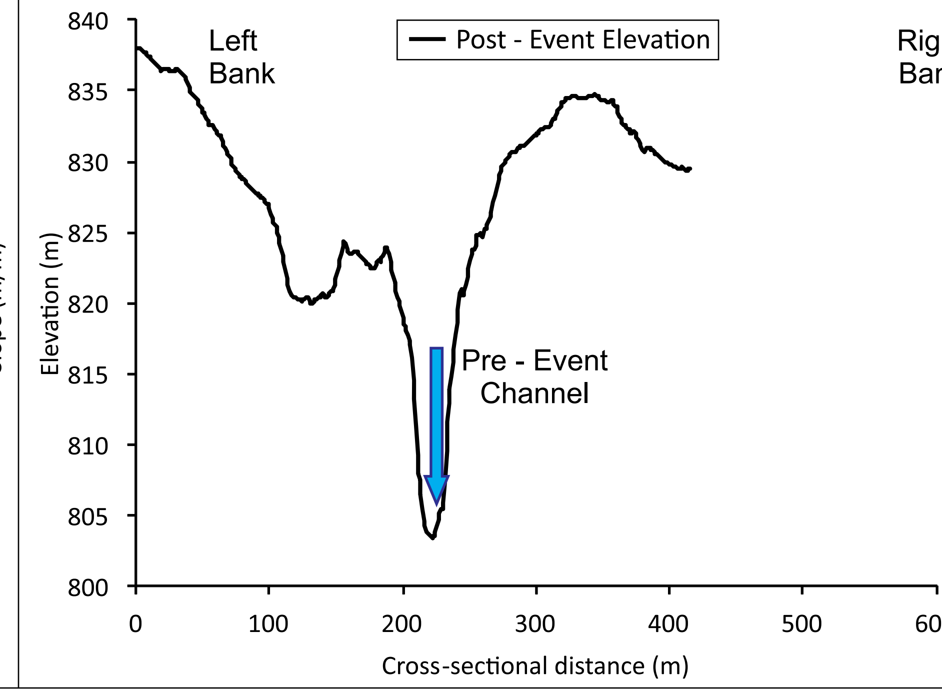


The Hazeltine Creek Canyon is a steep and narrow gorge cut into the surrounding bedrock

Long Profile



Cross Section



Typical Deposits and Surficial Material

Downstream view from the upstream entrance to the Hazeltine Creek Canyon. Banks are scoured to bedrock (September 26, 2014).

Bedrock waterfall present in the channel within Hazeltine Creek Canyon located just upstream of the lower Hazeltine Hydrometric station (October 10, 2014).

Fine gravel deposited on the Hazeltine Creek bed within the Canyon (October 10, 2014).

Hazeltine Creek Canyon looking upstream showing deposition of thin veneer of sand and fine gravel (October 10, 2014).

Key Features and Identified Impacts

Upstream entrance to the Hazeltine Creek Canyon showing exposed bedrock on Canyon walls (September 26, 2014).

Upstream view of Hazeltine Creek Canyon showing gorge scoured to bedrock (August 26, 2014).

Aerial view of the Hazeltine Creek Canyon walls showing scoured bedrock (September 5, 2014).

Right bank of the Hazeltine Creek Canyon showing scoured bedrock at surface (August 26, 2014).

Left bank of the Hazeltine Creek Canyons showing scoured bedrock at surface (August 26, 2014).

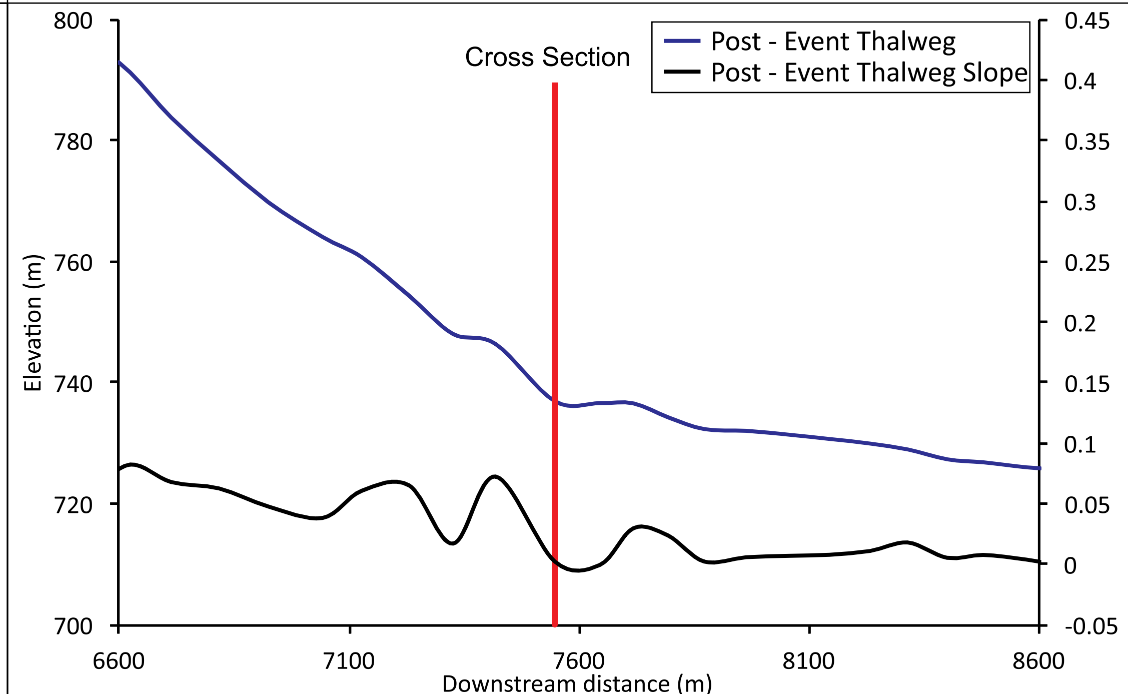
Aerial view of the Hazeltine Creek Canyon walls showing scoured bedrock (September 5, 2014).

REF No: REV: **0**	AREA:	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC·LAVALIN
621717-HIA-H010	**Lower Hazeltine Creek**	**HC-R7-R8**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	

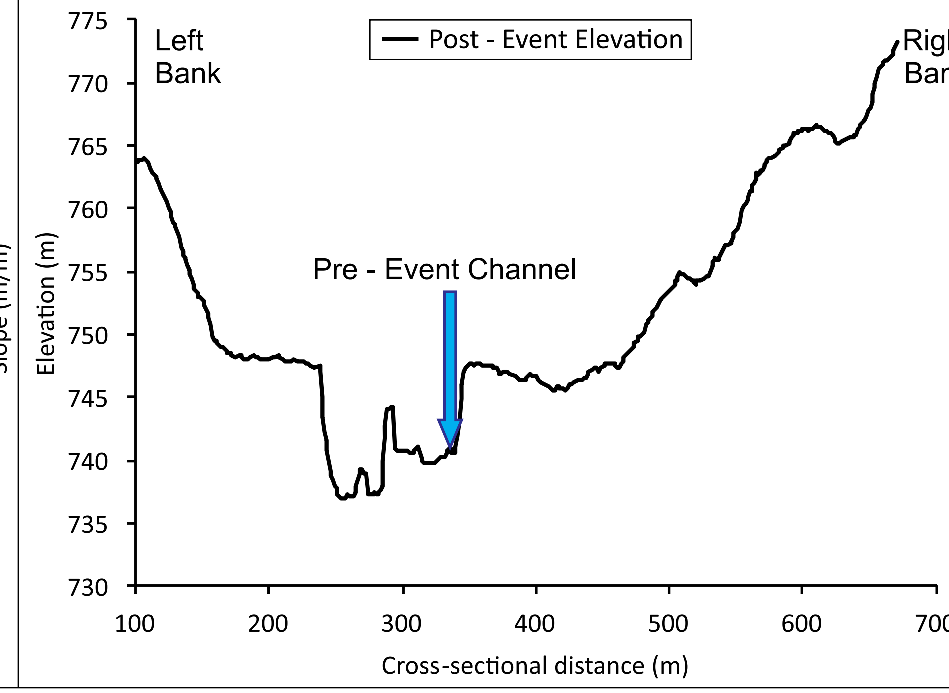
Area Overview

HC-R7-R8, located between the canyon and the confluence of Edney and Hazeltine Creeks, contains a large knick-point and a bifurcation in the debris flow.

Long Profile



Cross Section



Typical Deposits and Surficial Material

Aerial view towards the left side of the floodplain. The upper terrace is composed of native fluvial material, while the lower terrace is composed of lacustrine material (September 5, 2014).

View looking across the channel toward the right bank. A large knickpoint occurs in native till material (September 27, 2014)

Upstream view of the large knickpoint. The drop in elevation is as much as 4 m (September 27, 2014).

View from the top of the right bank. A thin layer of sandy tailings has been deposited on the surface (September 27, 2014).

Key Features and Identified Impacts

View of the left bank. Lateral erosion into the native lacustrine layer has led to undercutting and bank failures in the channel.

A highly sinuous meander incising into the bed downstream of the knickpoint. Flow is from left to right (September 26, 2014).

Downstream view of native fluvial deposits overlain by a thin layer of sandy tailings (September 27, 2014).

Downstream view of bank failures in the native lacustrine deposit (September 27, 2014).

Upstream view toward the knickpoint and the former Ditch Road bridge. Hazeltine Creek displays a braided channel form downstream.

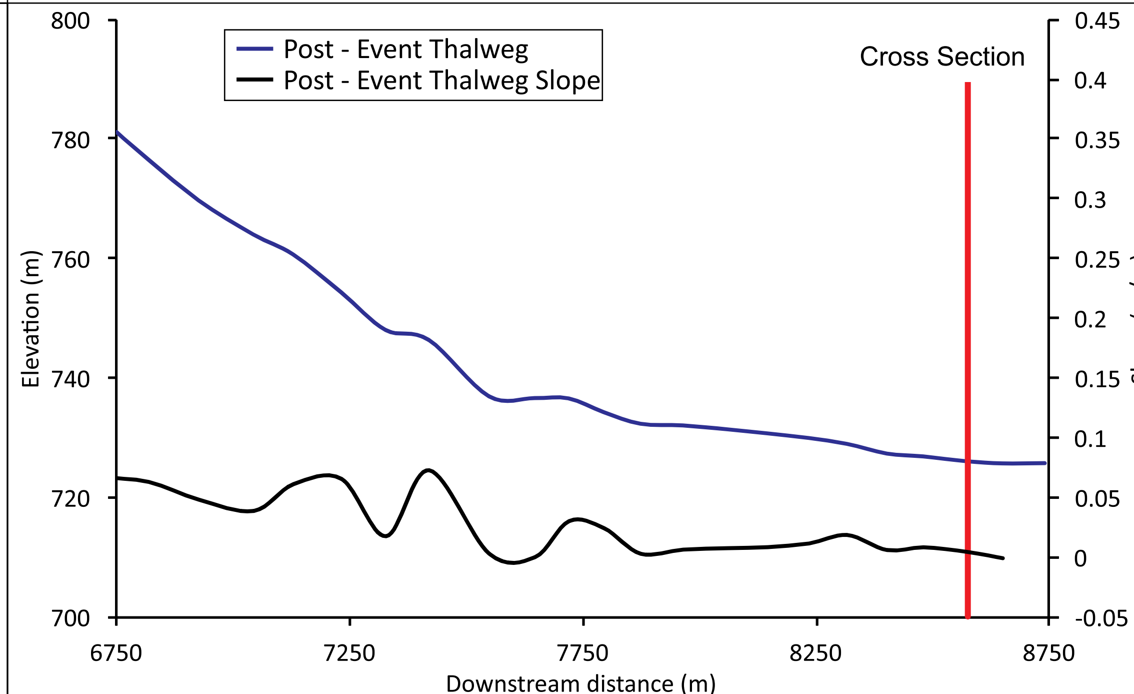
Upstream view from the top of the left bank. Event flow levels are preserved in the eroded terraces in the native fluvial material.

REF No: REV: **0**	AREA:	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC·LAVALIN
621717-HIA-H011	**Lower Hazeltine Creek**	**HC-R9**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	

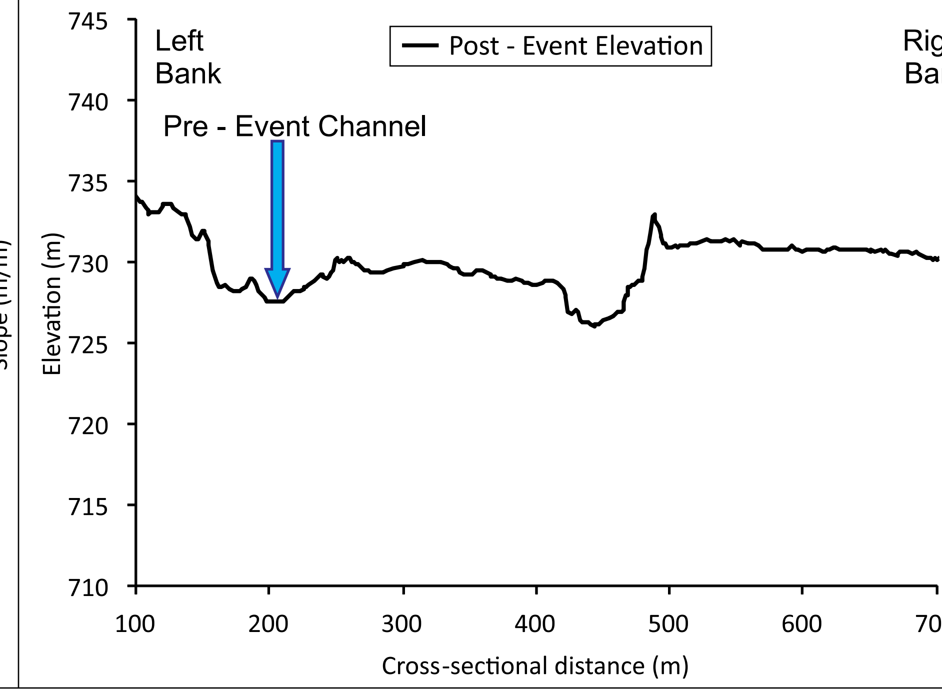
Area Overview

HC-R9 is located between the confluence of Edney and Hazeltine creeks and the outlet at Quesnel Lake

Long Profile



Cross Section



Typical Deposits and Surficial Material

Downstream view of the steep left bank. Stumps and root mats indicate the pre-event ground surface (September 27, 2014).

View of several terraces on the left bank of Hazeltine Creek near Quesnel Lake (September 27, 2014).

A large woody debris jam has been deposited at the upstream end of a tree island. View is downstream (September 27, 2014).

Large, cohesive blocks of material deposited on the floodplain near Quesnel Lake (September 27, 2014).

Key Features and Identified Impacts

Downstream view of the pre-event Hazeltine Creek channel at the left edge of the flood plain. The channel has avulsed and now flows on the right side of the flood plain (September 27, 2014).

Downstream view of the post-event Hazeltine Creek channel at Quesnel Lake, on the right side of the flood plain.

The post-event Hazeltine Creek channel is entrenched into native material. Pre-event elevation indicated by the tree stump.

Upstream view of the pre-event Hazeltine Creek channel (September 27, 2014).

Downstream view near Quesnel Lake. Most vegetation has been removed except for isolated tree islands (September 27, 2014).

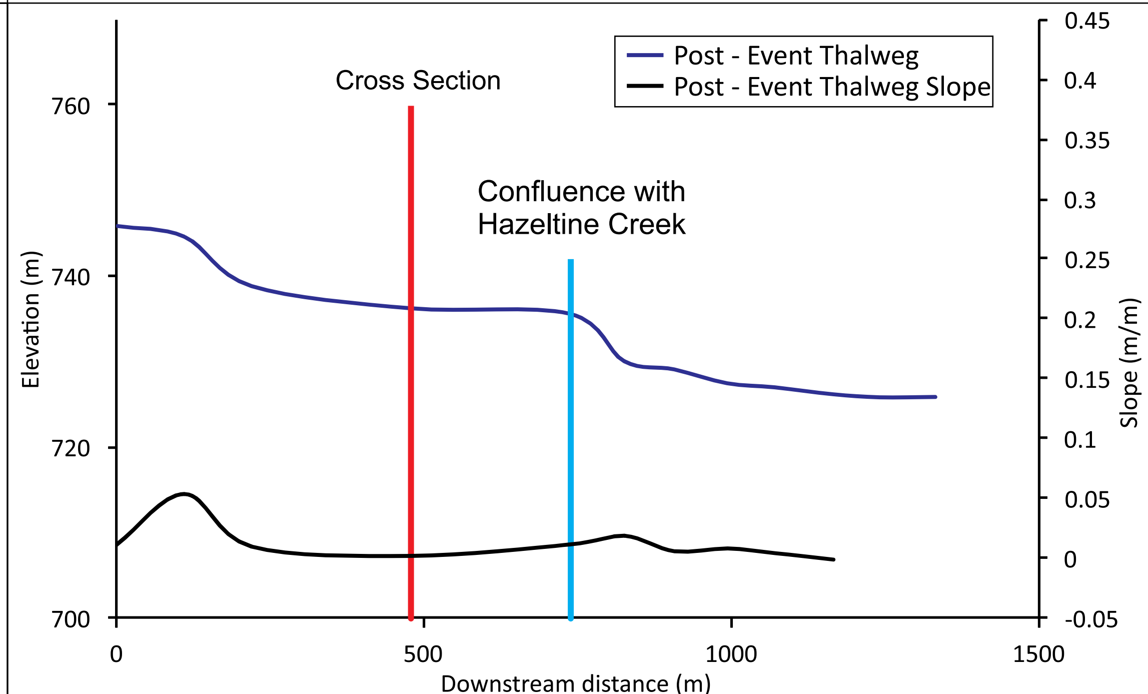
View near Quesnel Lake where large woody debris from the event has accumulated in the lake (September 27, 2014).

REF No: REV: **0**	AREA:	REACH:	CLIENT NAME:	PROJECT LOCATION:	DATE:	SNC • LAVALIN
621717-HIA-H012	**Edney Creek**	**EC**	**Mount Polley Mining Corporation**	**Mount Polley Mine, Likely, BC**	**2015/04/01**	

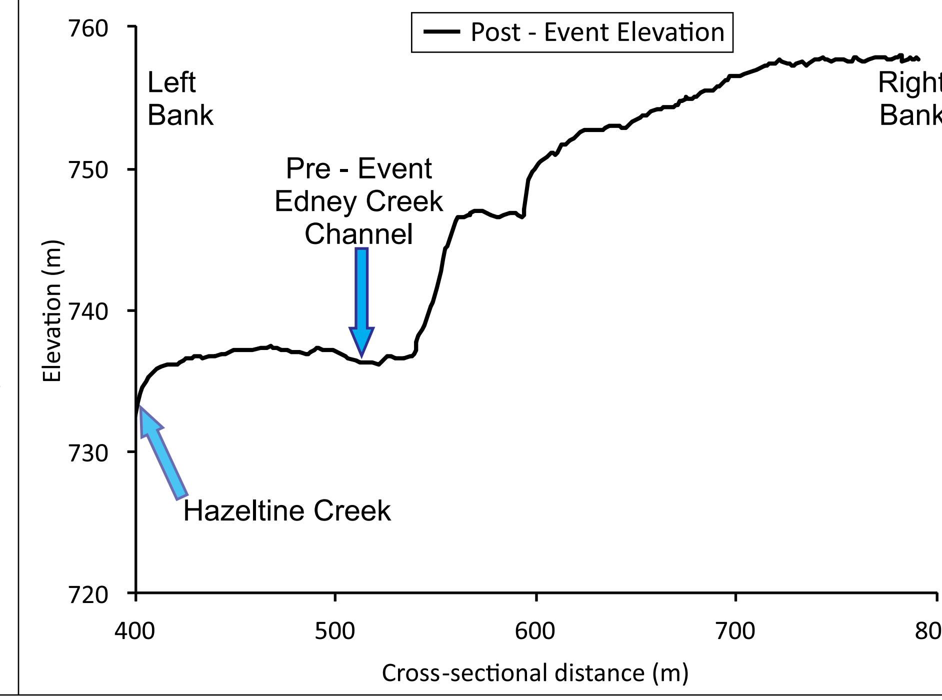
Area Overview

The affected area of Edney Creek extends 420 m upstream from the confluence with Hazeltine Creek. Near the confluence with Hazeltine Creek, Edney Creek is incised. Tailings are deposited within the channel above the incision.

Long Profile



Cross Section



Typical Deposits and Surficial Material

Upstream view from the confluence of Edney Creek and Hazeltine Creek. The channel is deeply incised into native material.

Downstream view of tailings deposited along Edney Creek channel (November 4, 2014).

Cutbank on Edney Creek exposing the sequence of native fluvial and glacio-fluvial deposits.

Incision of the Edney Creek channel into native material between the confluence with Hazeltine Creek and the Ditch Road Bridge (December 10, 2014).

Key Features and Identified Impacts

Upstream limit of affected area on Edney Creek (October 9, 2014).

Downstream view of the confluence of Edney Creek and Hazeltine Creek (December 10, 2014).

Upstream view of the confluence of Edney Creek and Hazeltine Creek (September 27, 2014).

Upstream limit of affected area on Edney Creek. Photo taken upstream of the ditch road bridge (November 3, 2014).

Channel incision and erosion of Edney Creek between the confluence with Hazeltine Creek and the ditch road bridge.

Edney Creek channel, upstream of the confluence with Hazeltine Creek (November 3, 2014).

USBL	Ultra Short BaseLine (Acoustic positioning system)
WSC	Water Survey of Canada

LIMITATIONS OF REPORT

This report and its contents are intended for the sole use of Mount Polley Mining Corporation and their agents. Tetra Tech EBA Inc. (Tetra Tech EBA) does not accept any responsibility for the accuracy of any of the data, the analysis, or the recommendations contained or referenced in the report when the report is used or relied upon by any Party other than Mount Polley Mining Corporation, or for any Project other than the proposed development at the subject site. Any such unauthorized use of this report is at the sole risk of the user. Use of this report is subject to the terms and conditions stated in Tetra Tech EBA's Services Agreement. Tetra Tech EBA's General Conditions are provided in Appendix A of this report.

1.0 INTRODUCTION

Mount Polley Mine is adjacent to Polley Lake, whose outflow forms Hazeltine Creek. About 8 km downstream of Polley Lake and the Mount Polley Mine, Hazeltine Creek enters the West Basin of Quesnel Lake. Quesnel Lake is a long, narrow fjord lake reaching from the Cariboo Mountains into the Interior Plateau of BC. Its average and maximum depths are 157 and 511 m, respectively, making it the deepest fjord-type lake in the world (Laval et al, 2008). It has a surface area of about 266 km^2 and a volume of 42 km^3. A contraction and sill at Cariboo Island, 21 km from the western end of Quesnel Lake, partially separates the main body of the lake from the so-called "West Basin," which represents 8.6% and 2.3% of Quesnel Lake's surface area and volume, respectively. With a mean annual outflow of 128 m^3/s through the Quesnel River, the whole lake has an average hydraulic residence time of 10 years, whereas the West Basin has an average hydraulic residence time of only 3 months.

Following the August 4, 2014 failure of the Tailings Storage Facility (TSF) at the Mount Polley Mine and the subsequent debris flow along Hazeltine Creek, suspended particulate material entered Quesnel Lake. Tetra Tech EBA Inc. (Tetra Tech EBA) was retained by Mount Polley Mining Corporation to perform both field measurements and numerical analyses to develop a predictive model that would evaluate the behaviour and fate of the suspended particulate material in Quesnel Lake. The modelling and field methods focussing on the lake's water column are detailed in the report "Quesnel Lake Water Column Observations and Modelling" (Tetra Tech EBA, 2015a).

Additionally, Tetra Tech EBA was requested to assess the overall volume balance of the failure event, giving consideration to all available sources of data, both on land and within Quesnel Lake. The bathymetry and sub-bottom profile data collected by Tetra Tech EBA in September 2014 are given particular attention. This report provides a synthesis of these data and presents a narrative and quantitative interpretation of the movement and fate of the displaced materials. The degree of uncertainty in estimated quantities is documented wherever possible.

2.0 FIELD METHODS

Field observations in Quesnel Lake involved water column profiling by MPMC and Tetra Tech EBA, bathymetric and geophysical data collection by Tetra Tech EBA, and sediment sampling carried out by Minnow Environmental Inc. (Minnow), supported by Tetra Tech EBA's research vessels. This report presents data collected by Tetra Tech EBA during a field program from August 28 to September 6, 2014, where the research vessels R/V Storm and R/V Ugle Duckling were mobilized from Tetra Tech's Bothell, WA, marine mapping group (Tetra Tech Bothell). Data collected in fall 2014 and early 2015 by a joint Mount Polley Mining Corporation (MPMC)/SNC-Lavalin water sampling and profiling program are also referenced. The water column profiling is described in detail in Tetra Tech EBA (2015a). Bathymetric, sidescan and sub-bottom profiling measurements are discussed in this report. A preliminary data report discussing bathymetric and geophysical methods and data collection, "Mount Polley Tailings Fate Survey" by Tetra Tech Bothell is attached as Appendix B, produced in September 2014. Any preliminary interpretation provided in Appendix B is superseded by this report.

2.1 Water Column Profiling

Water column profiles are the primary method of gathering physical limnological data. Conductivity, temperature, and depth (CTD) casts measure three parameters essential for understanding the vertical density structure of a water body. Profiling equipment used at Quesnel Lake also logged turbidity, an optical measure of water cloudiness, closely related to suspended sediment concentration. Collection of the water column profiles was a key objective of the August 28 to September 6, 2014, field program. Water column profiles were used to estimate the amount of suspended material in the water column on the observation dates. Profile data, methods, and results are reported in detail in Tetra Tech EBA (2015a).

2.2 Multibeam Bathymetry

The primary equipment mobilized onto the survey vessels included a multibeam echosounder sonar, side-scan sonar, sub-bottom profiler, acoustic Doppler current profiler (ADCP), CTD/turbidity sensor systems, and vessel positioning equipment. These systems and the ancillary positioning and vessel attitude systems that were used to conduct the seabed mapping are listed in Table 2.1 and discussed in more detail in Appendix B.

Table 2.1: Survey Equipment

Primary Equipment	Make/Model
Multibeam	RESON SeaBat 7125
Side-scan Sonar	EdgeTech 2000-DSS 100/600kHz chirp
Sub-bottom Profiler	EdgeTech 2000-DSS 2-16kHz chirp
ADCP	Teledyne RDI Workhorse Sentinel 600 kHz
USBL	IXBLUE GAPS
Positioning Systems	Applanix POS/MV 320, Trimble SPS65x with OmniStar
Heading, and Motion Reference Systems	Applanix POS/MV 320, IXBLUE GAPS
CTD with Turbidity	Seabird 19 Plus, YSI CastAway
Grab Sampler	WILDCO Standard Ponar (or similar)

The collected bathymetry data were processed with CARIS HIPS software to generate three dimensional maps in the survey coordinate system and units. Data quality control and assurance was also performed as described in Appendix B. The bathymetric chart produced by the multibeam survey is reproduced in Figure 2.1.

2.3 Sidescan Sonar

Additional data collected during the project included side-scan imagery sonar and sub-bottom profiler data from the towed EdgeTech 2000-DSS system. This system, referred to as a towfish, is connected to the vessel by a cable and allows measurements to be made closer to the lake bottom. These data provided detailed images of features and textures on the lake bed, and information on the subsurface stratigraphy below the profiler.

Side-scan sonar imagery were acquired in proprietary EdgeTech format (JSF) using EdgeTech's Discover acquisition software and then imported into Chesapeake SonarWiz 5 for post-processing. Towfish position from the acoustic positioning system (GAPS USBL) was recorded directly into the raw data file and/or HYPACK for geo-referencing all raw data. The SonarWiz processing package was used to remove erroneous navigation points, apply gains and conduct other signal processing, bottom track the data to remove the water column, and prepare the sonar data for final export. The imagery was exported from SonarWiz as 0.25-meter resolution geotiffs and is displayed on Figure 2.2.

2.4 Sub-Bottom Profiling

Sub-bottom profiler data were processed using the SonarWiz software. As with the side-scan sonar files, towfish position was acquired with the GAPS USBL and embedded in the raw data files acquired in the EdgeTech Discover and/or HYPACK programs. The files were recorded in the proprietary EdgeTech JSF format. The sub-bottom profile data were bottom-tracked and gains were applied where appropriate to distinguish different sediment layers on the lake bed where sediment layering was observed.

Penetration depth of the sub-bottom profiler provides information on sediment type and thickness. Areas that show distinct layering tend to be comprised of finer grained sediments such as fine sand, silt and clay because the sub-bottom profiler beam does not penetrate larger grained sediments such a coarse sand, gravel and cobble.

Selected sub-bottom profiles are shown and discussed in this report.

2.5 Acoustic Doppler Current Meter (ADCP)

ADCP data were collected and processed using the Teledyne-RDI WinRiver software. The ADCP transmits a set of four beams at different angles from vertical and measures the Doppler shift versus time from each beam to derive current directions and magnitudes at closely-spaced depths through the water column. It also tracks the return from the bottom to measure water depths and provides measurements of reflectivity versus depth in the water column that can be used to detect and delineate plumes of suspended sediment in the water column. The current data were used to help develop the hydrodynamic model and locate sediment plumes, but are not discussed further in this report.

2.6 Water and Sediment Sampling

MPMC conducted an extensive water column sampling program, discussed in detail in Golder (2015). Water was analyzed for physical parameters and metals. Laboratory results related to turbidity and suspended sediment concentration are discussed in Tetra Tech EBA (2015a). Long-term results from the suspended sediment modelling are discussed in Section 5 of this report.

3.0 EVENT VOLUME BALANCE

Before the dam failure, water normally flowed from Polley Lake into Hazeltine Creek and then into Quesnel Lake. The TSF dam failure discharge and subsequent debris flow entered Hazeltine Creek approximately 0.5 km downstream of Polley Lake and 8 km upstream of Quesnel Lake. The relatively flat terrain connecting the location of the TSF failure and the outlet of Polley Lake, and the great volume of discharge, allowed the initial surge to flow "upstream" into Polley Lake. This section seeks to reconcile the volumes of material that entered Polley and Quesnel Lakes with the debris flow discharge, deposit and scour volumes. A secondary goal of this section is to identify uncertainties in these estimates.

3.1 Discharged Volume

MPMC staff produced an estimate of the material lost from the TSF during the failure event based on prior survey data, TSF design, and water level data. The estimated volumes of released materials are as follows (MPMC, 2014):

- Supernatant water: 10.6 million m^3
- Tailings solids: 7.3 million m^3
- Interstitial water: 6.5 million m^3
- Construction materials: 0.6 million m^3

Thus, the total discharge volume is estimated at 25.0 million m^3 of liquid and solid materials combined.

Interstitial water refers to the water stored in between the individual grains of sediment in the TSF. The amount of interstitial water stored per amount of solids is termed the void ratio. The void ratio of soil can change: compaction or consolidation can reduce the void ratio, while mobilization such as a debris flow can increase the void ratio by mixing in additional water.

3.2 Polley Lake Volume Increase

The discharge entered Polley Lake, raising its level by 1.7 m (MPMC, 2015). Mount Polley Mining Corporation (2015) estimated that "approximately 6 million cubic metres of water flowed into Polley Lake." Independently, Tetra Tech EBA estimated the surface area of the lake as 3.77 km^2 based on aerial imagery; without allowing for an increase in surface area, the water level rise of 1.7 m thus implies a volume increase of 6.4 million m^3. Uncertainty in both these estimates comes from a lack of precise topographic data around the edge of the lake and from a lack of precise pre-event lake elevation. For the purposes of the volume balance, the MPMC estimate will be used, with an assumed uncertainty of ±0.5 million m^3. This volume is understood to be predominantly water (MPMC, 2015).

3.3 Quesnel Lake Volume Increase

Quesnel Lake has a water level gauge operated by Water Survey of Canada (WSC). Real-time data from this gauge, #08KH011, are available online, and showed an abrupt increase in lake level on August 4th, 2014. The lake level normally varies gradually due to seasonal patterns of inflow and outflow. By fitting straight lines to the observed lake level in the week surrounding the incident, it can be deduced that the sudden level increase was between 0.068 and 0.079 m (Figure 3.1). The river outflow and inflows are accounted for by the slopes of the fit lines; therefore, this level increase is due solely to additional materials that entered the lake as a result of the dam failure.

The observed lake level at the time was approximately 1.6 m on the gauge. At this level, the surface area of Quesnel Lake is approximately 267.5 km^2, indicating that the lake volume increased by between 19.7 ± 1.5 million m^3 as a result of the incident.

3.4 Hazeltine Creek Bed Volume Changes

Following the TSF dam failure, some material deposited almost immediately, forming a "plug" at the outlet of Polley Lake, while more of the material deposited in the bed of Hazeltine Creek. However, the debris flow also scoured some amount of native material out of Hazeltine Creek. These volumes were estimated by SNC-Lavalin (2015): the total volume of deposited material was approximately 1.6 ± 0.3 million m^3, while the eroded or scoured volume was 1.2 ± 0.6 million m^3. The estimated net deposition (i.e. deposition minus scour) on land is therefore 0.4 ± 0.9 million m^3.

On the time scale of the dam failure and subsequent debris flow – some hours – the water table within any deposited materials would likely not drop much below the surface due to the high fraction of fine tailings materials present. Scoured materials came from within or near the Hazeltine Creek bed, and were therefore likely saturated or nearly so. Therefore, for the purposes of this volume balance, the eroded and scoured volumes are both assumed to include a negligible volume of air in void spaces.

3.5 Volume Balance and Interpretation

Based on the above volumes, Tetra Tech EBA has estimated the general movement of displaced materials as follows:

- Construction materials from the dam (0.6 million m^3) deposited almost immediately, forming part of the plug at the outlet of Polley Lake.

- Some of the supernatant water (10.6 million m^3 total) went into Polley Lake (6 ± 0.5 million m^3) and the remainder went down Hazeltine Creek and entered Quesnel Lake (4.6 ± 0.5 million m^3).
- Some of the tailings solids and interstitial water (13.8 million m^3 total) contributed to the Polley Lake plug and other deposits: 1.0 ± 0.3 million m^3 makes up the balance of the deposited material (1.6 ± 0.3 million m^3 total). The remainder went down Hazeltine Creek and entered Quesnel Lake (12.8 ± 0.3 million m^3).
- Native material scoured from Hazeltine Creek also entered Quesnel Lake (1.2 ± 0.6 million m^3).

It is possible that some amount of tailings and interstitial water entered Polley Lake but this was not directly assessed by this study. The interpretation of primarily water entering Polly Lake is conservative from the perspective of maximizing the assumed volume of tailings, as opposed to water, that entered Quesnel Lake. Additionally, pre-impact bathymetry is of insufficient quality to enable quantification of Polley Lake depth changes. For the present purposes, it has been assumed that, effectively, Polley Lake received mostly water and the SNC-Lavalin (2015) volume estimates account for the solids deposition on the periphery of Polley Lake. Should it become possible to derive estimates for Polley Lake solids volume, then the Quesnel Lake solids volumes would be adjusted proportionally downward.

It is also possible that some volume of construction materials reached Quesnel Lake, which would imply a greater deposition of tailings materials on land, and correspondingly less in Quesnel Lake. The above interpretation assumes that the on-land deposition included all the construction materials, and is therefore conservative from the perspective of maximizing the assumed volume of tailings, as opposed to construction materials, that entered Quesnel Lake.

The above estimate specifies that the following volumes of displaced material entered Quesnel Lake through the debris flow:

- Supernatant water: 4.6 ± 0.5 million m^3
- Tailings solids and interstitial water: 12.8 ± 0.3 million m^3
- Native material from Hazeltine Creek: 1.2 ± 0.6 million m^3

The total volume estimated to have entered Quesnel Lake is therefore 18.6 ± 1.4 million m^3 by the above interpretation. This agrees well with the volume inferred from the lake level gauge, which indicated approximately 19.7 ± 1.5 million m^3. Of this total, solids and interstitial water make up approximately 14.0 ± 0.9 million m^3, and supernatant water accounts for the other 4.6 ± 0.5 million m^3.

4.0 BATHYMETRIC DATA ANALYSIS

4.1 2001 Bathymetric Survey

Coast Pilot Ltd. conducted a bathymetric survey of Quesnel Lake in October 2001 using an echo sounder and GPS with data logging software (Campbell, 2001). Sounding lines were spaced 1 km apart. The resulting bathymetric map and survey reference notes are reproduced in Figure 4.1. The raw data from the 2001 bathymetric survey were made available by the Institute of Ocean Sciences (Zotter, pers. comm.). The maximum surveyed depth in the West Basin was 121 m below the zero of the WSC gauge at Likely.

4.2 2014 Bathymetric Survey

A new and more detailed multibeam bathymetric survey was carried out by Tetra Tech EBA in the West Basin of Quesnel Lake in from August 30 to September 6, 2014, as described in Section 2.2. This survey had complete coverage within the 60-m depth contour of the West Basin and partial coverage north to Cedar Creek and east beyond Plato Island (see Figure 2.1). The maximum surveyed depth in the West Basin was 108 m below the zero of the WSC gauge. Figure 4.2 shows depth contours (lines) and a slope map (shading) derived from these survey data. The shading indicates the slope of the lake bottom, with lighter shades indicating a flat bottom and dark shades representing steeper slopes. Changes in slope are useful in delineating erosion and deposition features, discussed below.

4.3 Comparison of 2001 versus 2014 Bathymetry

Tetra Tech EBA compared the new (2014) and old (2001) bathymetry data by interpolating the new data onto the old survey points, and correcting to a common datum (taken as the zero of the WSC level gauge at Likely). The pattern of soundings taken in 2001 allows the reconstruction of both transverse and longitudinal sections in the area of interest. The inset map on Figure 4.3 shows the locations of the 2001 soundings, while the panels labelled "Section V" and "Midline 1" show vertical cross-sections along the corresponding lines (highlighted in yellow on the inset map). In the deepest portion of the West Basin, there are obvious depth changes between 2001 and 2014. From the "Midline 1" section (Figure 4.3), an infill or decrease in depth of at least 10 m is apparent, from Sections F through I. There is also a step of about 4 m in the 2014 bottom elevation just north of Section H, which will be discussed later.

In the main body of the lake, where no significant event deposition is expected, the 2001 and 2014 bathymetry agree closely. For example, the old and new bathymetry along Section V are almost indistinguishable visually (Figure 4.3). A point-by-point comparison of the depths on Section V shows a root-mean-square depth difference of 3.1 m and an average difference of 0.5 m. These differences can be attributed to the inaccuracies inherent in the respective surveying methods.

The four West Basin sections with maximum depth greater than 100 m are shown in Figure 4.4, with an inset map indicating their locations. Note the change of vertical scale from Figure 4.3. Sections F, G and I show a clear similarity in overall shape between 2001 and 2014, with a horizontal shift of about 50 m suggested. This horizontal shift is likely an artifact of 2001-era surveying and GPS accuracy and is not of consequence in the present study. However, in these three sections the West Basin has become shallower due to recent deposition of solid materials.

It is worth observing here that the Midline 1 sounding track did not follow the thalweg, or line of greatest depth, in the West Basin (see Section G in Figure 4.4, for example). This means that Midline 1 does not reflect the full degree of infill at all locations.

The comparison of bathymetry along section H, adjacent to the Hazeltine delta, shows a 60 metre difference in bathymetry on the western side. Confidence in the 2001 data along this section, and their interpretation, is substantially undermined by the 2001 bathymetric map, in which the surveyor plotted the 100-m contour line through the shallower data points around 40 m depth (see Figures 4.1 and 4.4). Tetra Tech EBA contacted the surveyor, who acknowledged that there was evidently an error of some sort at that location. Thus, these data points are not relied on in this document to draw any quantitative conclusions.

4.4 Estimation of West Basin Volume Changes

The volume of the West Basin below the 100-m contour can be estimated from both the 2001 data and the 2014 data. Interpolating between sections F, G and I (thus excluding section H), Tetra Tech EBA estimated volumes based on both data sets and found the volume to be approximately 18 million m^3 less in 2014.

In seven other sections where no deposition is expected, the typical disagreement between 2001 and 2014 bathymetry is about 1000 m^2 in the cross-sectional area of the bottom 15 m of a given section. Since the volume change happened in a region about 5 km long, the estimated uncertainty in the volume difference is ±1000 m^2 x 5 km = ±5 million m^3, or ±30%.

In summary, the comparison between 2001 and 2014 bathymetry data in the West Basin shows definite deposition below the 100-m contour. The deposited material is likely a combination of solids that entered the lake after the TSF dam failure and redistributed material from underwater erosion (discussed in Section 4.6 below) of the underwater lake sideslope below the Hazeltine area. The relative proportions of these materials are addressed below.

4.5 Discussion of 2014 Sub-bottom Profiler Data

In 2014, Tetra Tech Bothell conducted a sub-bottom profile survey of the West Basin in the vicinity of Hazeltine Creek. The sub-bottom profiler data and field interpretation are discussed in Tetra Tech Bothell's report (Appendix B). This section is concerned with comparing and reconciling the sub-bottom profiler data with the bathymetry changes discussed above. Interpretation in this report supersedes the Appendix B report due to additional available information and analysis. Sub-bottom imagery is best interpreted relative to other observations, such as previous surveys or boreholes, as sub-bottom reflectors could be either recent (event-related) or much older soil horizons. In this case, the 2001 survey provides data on former lake bed depth and improves understanding of the sub-bottom reflectors. The sub-bottom profiles show approximate depth (with 0 being at the water surface on the day of the survey) on the vertical axis and along-track distance on the horizontal axis; with both axes in meters.

Figure 4.5 shows the survey tracks of the sub-bottom profiles collected in 2014, overlaid with the positions of the 2001 depth soundings. Tetra Tech Bothell's report provided sub-bottom profiler imagery for those portions of the tracklines indicated with magenta rectangles (Figure 4.5). Trackline "Line 04" is approximately parallel to and slightly west of the 2001 soundings along Midline 1, and proceeded from southeast to northwest.

Imagery for profiles 4-1 and 4-2 is reproduced in Figure 4.6. Note that these profiles are presented from the point of view of an observer on the northeast bank of Quesnel Lake, looking back toward Hazeltine Creek. Higher acoustic reflectivity is shown in darker colours. Bedrock and coarse sediments are more difficult for the acoustic signal to penetrate, and appear as a single surface with no distinct reflective layers beneath. Fine-grained sediments appear as a series of reflective layers.

Profile 4-1 (Figure 4.6) is near the intersection of Midline 1 and Section I, in which the bathymetry comparison showed an infill of approximately 10 m (see Figures 4.3 and 4.4). Profile 4-1 shows over 10 m of fine-grained sediments likely deposited on the southeast part of the profile, with the upper surface of the deposited material at approximately 100 m depth. This observation agrees closely with Midline 1 and Section I, which also show an upper surface near 100 m depth. As the survey vessel continued northwest the profile line intersected the underwater lake sideslope, which appears as a raised feature.

Profile 4-2 is offshore of the Hazeltine delta, near the intersection of Midline 1 and Section H (see Figure 4.5). This profile indicates coarse-grained sediment rather than fine-grained, but still with an upper surface around 100 m depth (Figure 4.6). Moving from southeast to northwest there is a noticeable step down of about 3-4 m at the edge of the coarse-grained deposition area. This observation matches Midline 1, which also shows a step down at this location. This makes physical sense as the higher-relief area is closer to the Hazeltine source, and coarser material sinks faster and would therefore tend to deposit near the source.

Profile 4-3 is north of the Hazeltine delta, near the intersection of Midline 1 and Section G (see Figure 4.5). This sub-bottom profile shows over 10 m of fine-grained likely sediments deposited (Figure 4.7), with an upper surface around 104 m depth and a lower surface below 115 m depth. These depths agree with Section G (Figure 4.4), although profile 4-3 appears to be east of the deepest part of the section.

Trackline “Line 10” lies between the lake’s shoreline and Line 04, along the underwater lake sideslope at intermediate depth (see Figure 4.5), proceeding from northwest to southeast (Note: opposite to Line 04). Profile 10-1 (Figure 4.7) crosses through Section H over what appears to be a deltaic depositional cone formed by Hazeltine Creek prior to the TSF dam failure. No differentiable deposition of fine-grained material is evident except at the southeast end of the profile beyond the edge of the depositional cone.

Profiles 10-2 and 10-3 (Figure 4.8) are offshore of the Hazeltine delta near the middle and the southeast extent, respectively, of the visibly eroded underwater lake sideslope (see Figure 4.5). These two profiles each show channels in the underwater lake sideslope which appear to have been scoured out or destabilized by an underwater debris flow during the event. The channel visible in profile 10-2 is about 20 m deep by 250 m wide, while that in profile 10-3 is about 5 m deep by 100 m wide. The reflectors to the sides of the scoured channels in profiles 10-2 and 10-3 are interpreted as pre-existing lake bed deposition having occurred over geologic time scales, as this pattern of layers appears repeatedly on sections more distant from the Hazeltine area (not shown).

The coarse-grained sediments observed in profile 4-2 (Figure 4.6) are offshore of the channel in profile 10-2, which implies that underwater lake sideslope erosion occurred in channelized fashion, quickly depositing in the area around profile 4-2. During this erosion event, the underwater lake sideslope materials would have become mixed with the displaced materials from the TSF and Hazeltine Creek, resulting in a mixed-composition deposit. The step in profile 4-2 and Midline 1 appears to be the edge of the coarse-grained deposit from this phase of the underwater debris flow.

4.6 Estimation of Underwater Lake Sideslope Scour Volumes

The scour channels visible in sub-bottom profiles 10-2 and 10-3 are identifiable in the 2014 bathymetric data from the uppermost limit of the survey at about 20 m depth, down to about 85 m depth, at which point the channel shapes intermingle with the depositional fans.

Assuming that the underwater lake sideslope was previously smooth, it is possible to estimate the volume missing from the scour channels. At the 30-m depth contour, for example, Tetra Tech EBA traced the contour line along the base of the scour channel and then connected the upper edges of the channel with a straight line, forming a closed polygon. This technique was repeated for each contour at 5-m intervals from 20 to 85 m depth, and for both scour channels. Figure 4.9 shows example polygons in each scour channel at depth contours of 30 and 55 m.

At the water surface, some degree of shoreline recession is evident in aerial photographs. Tetra Tech EBA delineated the shoreline before and after the event, using aerial imagery, and found the difference in land area to be approximately 45,000 m^2. This differs from the SNC-Lavalin (2015) figure of 32,200 m^2 because Tetra Tech EBA included the Hazeltine mouth and traced the waterline further upstream the new Hazeltine channel, while SNC-Lavalin reported upstream Hazeltine changes elsewhere in their report.

Finally, the areas of the shoreline recession and scour channel polygons were integrated over depth to calculate an estimated total volume of material displaced from the channels. The total scoured volume is approximately 1.9 million m^3, according to this method. The scour channels visible in sub-bottom profiles 10-2 and 10-3 account for approximately 80% and 20% of the total, respectively. This method, however, suffers from the questionable assumption of straight contours prior to the scour event(s). Judging from the shoreline shape prior to the TSF dam failure, the contours could be drawn somewhat concave, possibly eliminating half of the "lost" volume. The scoured volume is therefore most probably between 1.0 and 2.0 million m^3, and will be quoted as 1.5 ± 0.5 million m^3.

4.7 Estimation of Underwater Lake Sideslope Deposition Volumes

There is little evidence of deposition on the underwater lake sideslope offshore of the debris flow paths on land. Large volumes of displaced material would not be expected to deposit on these banks, which are as steep as, or steeper than, the natural Hazeltine fan. The sub-bottom profiler did not show a distinguishable layer of deposition on the Hazeltine fan. The reflectors outside of the scoured channels in Profiles 10-2 and 10-3 are interpreted as pre-existing lake bed deposition having occurred over geologic time scales. Even if an event-related deposited layer of 1-m thickness is assumed, the deposition on the fan would be only 0.05 million m^3. For the purposes of the in-lake volume balance, underwater lake sideslope deposition is assumed to be negligible.

4.8 Discussion of Underwater Processes

An underwater debris flow, or turbidity current, is a coherent body of water which descends a slope under the weight of its suspended sediment load. The TSF dam failure produced a debris flow on land in the Hazeltine Creek channel(s), which continued underwater creating the channels discussed in Section 4.6.

There are two phases of the underwater debris flow discussed in this report, distinguished by the amount of energy available to transport sediment. The amount of energy available to transport sediment increases with the steepness of the slope and with the difference in density between the debris flow and the ambient water. The high-energy phase of the underwater debris flow occurred on the underwater lake sideslope between the shoreline and the relatively flat lake bottom below 100 m. The steepness of the slope allowed this phase of the debris flow to carry all sediments, including fine and coarse tailings and the coarsest native material scoured from above and below the waterline, to the depositional area generally below the 100-m contour. The area affected by this high-energy debris flow, including the flow paths and the depositional zone of the coarse materials, is indicated by the orange dashed line in Figure 4.10, which delineates and area of approximately 0.39 km^2, and includes both erosional and depositional features.

The low-energy phase began at the foot of the scour channels in the underwater lake sideslope after the coarse material deposited, and finer sediments spread gradually in both directions along the axis of the West Basin. The available slopes and density differences were both much less in this phase of the flow, and therefore it is likely that only finer sediments were transported. Figures 4.2 and 4.10 outline the estimated depositional zone of this low-energy debris flow with a green dashed line. The area of event-related infill within the estimated depositional zone is 1.81 km^2 based on data from the bathymetric analysis and sub-bottom profiling of sediment layers. Figure 4.11 schematically illustrates the high- and low-energy debris flow paths over a three-dimensional view of the Hazeltine delta. The timing of these flow phases is not known from the available information.

The two scour channels discussed in Section 4.6 appear to be connected with debris flows at somewhat different energy levels. The debris flow coming down Hazeltine Creek would have had the greatest energy at or near the beginning, when it was carrying the largest volumes and included the coarsest materials. Hours later it would have carried lower volumes and predominantly water and finer material. The channel shown in Profile 10-2 (Figure 4.8) is directly offshore of the Hazeltine Creek and Edney Creek confluence, and it seems that the flows with the highest momentum and energy would have forced a path to that point for discharge to the lake. The alignment of this channel with the on-land flow path is apparent in the three-dimensional view shown in Figure 4.11. Once the energy level decreased, the on-land Hazeltine channel (discussed in SNC-Lavalin (2015)) appears to have veered to the south, and begun discharging into the lake above the underwater channel shown in Profile 10-3 (Figure 4.8) and shown on the left in Figure 4.11.

4.9 In-Lake Volume Balance

The on-land volume balance (Section 3.5) indicated that the total volume of material that entered Quesnel Lake was approximately 18.6 ± 1.4 million m^3, of which 14.0 ± 0.9 million m^3 was solids and interstitial water. In fact, the on-land debris flow would have caused some degree of mixing, likely entraining some of the supernatant water, effectively converting it to interstitial water.

The underwater debris flow would have continued mixing, entraining ambient water into the flow as well as scouring coarse native material from the underwater lake sideslope. The scoured coarse material was estimated at about 1.5 ± 0.5 million m^3. Adding this to the 14.0 ± 0.9 million m^3 of solids and interstitial water, the total volume of the debris flow reaching the bottom of the West Basin was approximately 15.5 ± 1.4 million m^3 plus an unknown volume of entrained ambient water. This agrees with the estimated volume of deposited material as of early September 2014, which was 18 ± 5 million m^3 (Section 4.4).

As deposited fine sediments consolidate, some of the entrained water and interstitial water seeps out. Therefore, as time progresses, the apparent volume of the deposited material will likely decrease.

5.0 DISCUSSION OF SUSPENDED MATERIAL

Some of the material entering Quesnel Lake consisted of very fine-grained material, which takes much longer to sink than coarser material such as sand, or even most silts. Tetra Tech EBA (2015a) discusses field observations, analytical estimates, and numerical modelling of the suspended material present in Quesnel Lake's West Basin due to the TSF failure and subsequent debris flow. The modelling results relevant to the event volume balance are summarized in this section.

5.1 Suspended Material Modelling

Tetra Tech EBA (2015a) estimated the amount of material suspended in the water column on three observation dates based on water column stability for a lower bound, and laboratory analysis of water samples for a more conservative (higher) value to use as a model initial condition. The suspended mass estimates in Quesnel Lake are reproduced in Table 5.1, along with the conversion to cubic metres based on an assumed mineral density of 2650 kg/m^3. Even the highest estimate of suspended sediment is only 0.025 million m^3 –small compared with the erosional and depositional volumes measured and estimated throughout this report.

Table 5.1: Suspended Sediment Mass

	Lower Bound (kg) (based on stability considerations)	Lower Bound (million m^3)	Model Initial Condition (kg) (based on laboratory analyses)	Model Initial Condition (million m^3)
August 13	28.8 - 37.8 x 106	0.011	65.5 x 106	0.025
September 1	23.7 x 106	0.0089	41.8 x 106	0.016
October 24	7.7 x 106	0.0029	12.4 x 106	0.0047

The three-dimensional hydrodynamic model described in Tetra Tech EBA (2015a) was initialized with the above total suspended mass estimates, based on three sets of observations in August, September and October 2014. Each model implementation simulated the three-dimensional processes of sediment transport, settling and deposition, horizontal and vertical mixing, and river inflows and outflows.

The models using August and September initial conditions, where much of the suspended material was still in the water column near the bottom of the West Basin, provide the most conservative predictions of the material's fate. Figure 5.1 shows a line plot of the modelled mass balance for the time period September 1, 2014 to December 31, 2015. The model was initialized with 41.8 x 10^6 kg (sediment mass corresponding to 0.016 million m^3*)* of suspended sediment distributed throughout the lake based on a weeklong CTD and turbidity profiling program (Section 2.1). Some suspended material had already exited the West Basin via the Cariboo Island sill and was found in the water column between Cariboo and Plato Islands. Therefore the model started with ~18% of the suspended material already in the main body of the lake.

In the months of September and October 2014 a small amount of suspended material exited via the Quesnel River in wind-driven seiche events, where the lower level of the lake tilts to meet the surface at, in this case, the north end. Most of the decrease in the West Basin water column is likely due to wind events driving occasional outflows of material over the Cariboo Island sill, combined with a steady settling of the suspended material in the West Basin, indicated by the exponential decay form of the deposition time series (Figure 5.1).

The mixing of the water column in November and December 2014 brought suspended material to the surface, where it began to flow out the Quesnel River. The cumulative volume of suspended material flowing out the river increased starting in mid-November, and is predicted here and in Tetra Tech EBA (2015a) to stabilize again in spring 2015.

The distribution of material at the end of the 16-month simulation starting September 1 is presented as a pie chart in Figure 5.2. There is a range in the predictions depending on whether the August 13 or September 1 model is used. The models predict that by summer 2015, between 15% and 20% of the original amount of suspended material will have left Quesnel Lake via Quesnel River. 40% to 50% of the material has settled in the West Basin, and 35-40% of the material has been transported to the main body of the lake and either has settled or is in the process of settling, but remains in the water column at low concentrations covering a wide area.

Uncertainty

Uncertainty regarding the amount of suspended material in the water column is discussed in more detail in Tetra Tech EBA (2015a) but in summary the minimum volume estimates are an absolute lower bound, and the modelled initial condition represents an estimate based on turbidity to TSS (total suspended sediment) scatter plots with ±40% scatter around the best fit line.

There is uncertainty regarding the composition of suspended material and its rate of deposition. Comparison of the two models with August 13 and September 1 start dates, and subsequent measurements and volume estimates provide an indication of the suspended volume balance uncertainty.

The September 1 model started with 41.8 x 10^6 kg of sediment suspended in the water column, 35.2 x 10^6 kg of which was in the West Basin. On October 25, the model indicated that 15.9 x 10^6 kg of material remained suspended in the West Basin. The analytical estimate of material in the West Basin water column on the same date was 9.3 x 10^6 kg (Tetra Tech EBA 2015a).

The model validation to observed turbidity in the Quesnel River provides relatively high certainty in the predictions of total flux out the Quesnel River. Therefore, the model's overestimate of material remaining suspended in the West Basin indicates the model likely underestimated either West Basin deposition or transport across the sill. Recent low turbidity observations in the West Basin support the conclusion that more fine suspended material left the West Basin water column via either settling or transport to the main body of the lake.

5.2 Comparison with Natural Sediment Loads

Approximately 20% of the suspended material from the August 13 and September 1 model's initial condition was predicted to exit the lake via the Quesnel River, and another 40% was predicted to cross the sill into the main body of the lake. The August 13 initial condition contained the highest mass, 65.5 x 106 kg, of suspended material; therefore, the model predicted approximately 13 x 106 kg would exit via the river, and 26 x 106 kg would enter the main body of the lake.

Tetra Tech EBA estimated the annual sediment load in the Quesnel River from TSS concentrations reported by Perrin and Blyth (1998). They compiled sediment data and reported median, mean and maximum TSS concentrations in the river as 2.0, 14.55 and 692 mg/L, respectively, from 190 data points. The raw data were not available. These statistics suggest that samples were taken both on and off freshet, possibly year-round. Data available from WSC, up to 2012, indicate the average annual flow in the Quesnel River near Quesnel is about 230 m3/s. At the mean TSS concentration, this annual flow would transport 106 x 106 kg of sediment. Since TSS concentration is usually associated with high flows, use of the average flow and concentration will tend to underestimate the annual sediment load. Therefore, 106 x 106 kg should be considered a lower bound to the river's sediment load.

The modelled discharge of 13 x 106 kg of suspended material to the Quesnel River following the TSF dam failure represents 12% or less of the river's annual sediment load.

Tetra Tech EBA also estimated the annual sediment load entering Quesnel Lake through Niagara Creek, which generates a visible turbidity plume where it enters the lake during freshet. The plume was observed by Potts (2004) to extend 420 m along the shore. James (2004) took samples throughout the lake including within the Niagara Creek plume, and directly measured the sample density as well as water chemistry. Assuming a solids density of 2650 kg/m3, the difference between the Niagara samples' bulk density and liquid density implies a suspended sediment concentration of 81 mg/L. The samples were taken during freshet, on June 23, 2004. Following the hydrologic methods of Potts (2004), the average annual flow in Niagara Creek is estimated to be 29.5 m3/s with a freshet flow around 82 m3/s. Assuming a three-month freshet, James's data suggest an annual sediment load of about 50 x 106 kg may enter Quesnel Lake through Niagara Creek.

The modelled escape of 26 x 106 kg of dilute suspended material from the West Basin into the main body of the lake following the TSF dam failure is about half the amount of suspended sediment discharged into the East Arm annually by Niagara Creek.

6.0 CONCLUSIONS

Tetra Tech EBA used a research vessel equipped with geophysical and survey equipment to measure the bathymetry of the West Basin of Quesnel Lake. An acoustic instrument called a sub-bottom profiler was also used to detect layers of sediment on the lake bottom.

MPMC estimated that 25.0 million m^3 of material was discharged from the TSF as a result of the dam failure. This total was comprised of 10.6 million m^3 of free water, 13.8 million m^3 of tailings solids plus interstitial water, and 0.6 million m^3 of construction materials.

Based on an observed increase in Polley Lake level after the TSF dam failure, MPMC estimated that 6 ± 0.5 million m^3 of water entered Polley Lake.Based on the observed increase in Quesnel Lake level, Tetra Tech EBA estimated that 19.7 ± 1.5 million m^3 of solids and liquids entered Quesnel Lake.

SNC-Lavalin estimated deposition and erosion volumes in the terrestrial affected areas on land based mapping of surface materials, cores, soil pits, trenches and channel cross-sections. Lack of pre-event data imposes some uncertainty on this analysis. The estimated volumes were 1.6 ± 0.3 million m^3 of deposition, predominantly near Polley Lake, and 1.2 ± 0.6 million m^3 of erosion, predominantly in the middle reaches of Hazeltine Creek.

By Tetra Tech EBA's interpretation, the materials released from the TSF were distributed as follows. Of the free water, 6.0 ± 0.5 million m^3 went into Polley Lake, and the remainder went into Quesnel Lake (4.6 ± 0.5 million m^3). Of the construction materials (0.6 million m^3), essentially all were deposited on land. Of the tailings solids and interstitial water, about 1.0 ± 0.3 million m^3 were deposited on land, and the remainder went into Quesnel Lake (12.8 ± 0.3 million m^3). Adding the material scoured from Hazeltine Creek, therefore, the total amount of displaced material that entered Quesnel Lake was 18.6 ± 1.4 million m^3, which agrees, within the bounds of uncertainty, with the volume estimated from the water level increase.

Based on differences between the observed 2001 and 2014 bathymetry in the West Basin, Tetra Tech EBA estimates that approximately 18 ± 5 million m^3 of displaced material deposited below the 100-m contour, as a result of the TSF dam failure event. This volume is expected to decrease over time as the fine sediments consolidate, releasing some of their interstitial water.

Analysis of the underwater lake sideslope shape suggests that about 1.5 ± 0.5 million m^3 of native material was eroded by underwater debris flows. For the purposes of this volume balance, deposition on the underwater lake sideslopes was negligible. Together with tailings solids, interstitial water and scoured Hazeltine material, a total of 15.5 ± 1.4 million m^3 of displaced material likely reached the bottom of the West Basin. This agrees with the observed depositional volume, based on lake water level change, within the range of uncertainty. Some of the discrepancy between the deposition volume estimates may also be explained by the entrainment of additional interstitial water during the debris flows, both on land and under water. The area of event-related infill within the estimated depositional zone is 1.81 km^2 based on data from the bathymetric analysis and sub-bottom profiling of sediment layers.

The volume of material that remained in suspension in the West Basin after the event was estimated by Tetra Tech EBA to be between 0.01 and 0.025 Mm^3 (28.8 to 65.5 x 10^6 kg) based on profiles of temperature and turbidity on August 13, 2014. Tetra Tech EBA's three-dimensional hydrodynamic model predicts that by summer 2015 up to 20% of this material will have exited the lake via Quesnel River, and up to 40% will have been transported to the main body of the lake at low concentration. For comparison, the Quesnel River's natural annual sediment load downstream of Quesnel Lake near Quesnel is at least 8 times the amount of material predicted to have escaped as a result of the TSF dam failure. The natural annual sediment input to the main body of Quesnel Lake via Niagara Creek is approximately double the amount of material predicted to have dispersed into the main body of the lake as a result of the TSF dam failure.

7.0 CLOSURE

REFERENCE NOTES

1. This drawing is based on the Transverse Mercator Projection with UTM Grid Zone 10,Central Meridian 123 - 00 - 00W.
2. Horizontal Datum is North American Datum 1983 (NAD 83).
3. Sounding Datum was determined from water level observations by Environment Canada for the years 1956- 1999. Sounding Datum was set to the lowest yearly water level for these years, which was 0.10 metres above the e the zero of the Water Survey of Canada gauge at Lickley. The water level above sounding datum during the time of the survey was 0.70 metres.
4. Bench Mark M01c9002 was established on the East side of a concrete launching ramp at Elysia Resort. The elevation of this Bench Mark is 2.914 metres above Sounding Datum.
5. Soundings were obtained with a Knudsen 320M dual frequency echo sounder operating at 38 kHz and set at 1500 m/s. The draft was set to 0.2 metres and a mean speed of sound in the water as measured by an Odom Velocimeter (1425m/s). Draft, water level and speed of sound adjustments were applied during processing. All soundings portrayed are true depths.
6. Off-shore soundings were positioned using an Ashtech G12 High Accuracy Differential GPS Beacon Receiver
7. Survey operations were conducted in October 2001.
8. Sounding lines were spaced 1000 metres apart. This line spacing is not suitable to detect all under water hazards with confidence. This Drawing is not suitable for marine navigation.
9. Depths and positions were logged using Hypack Max (Version 00.5a) navigation and logging software.
10. Coastline comes from the BC Ministry of Environment, Lands and Parks "Terrain Resource Information Management" (TRIM) initiative maps. The coastline was validated during the field survey.
11. Depths are in metres reduced to chart datum. One Hundred metre contours are shown.
12. The contours were compiled from a larger data set than shown. Volume calculations determined the Volume of the Lake system to be 41,533,401,900 cubic metres.
13. Navigational Aides were surveyed by GPS.
14. Place Names have been compiled from Department of Fisheries and Oceans documents, Topographic maps and consulting with Local Residents.

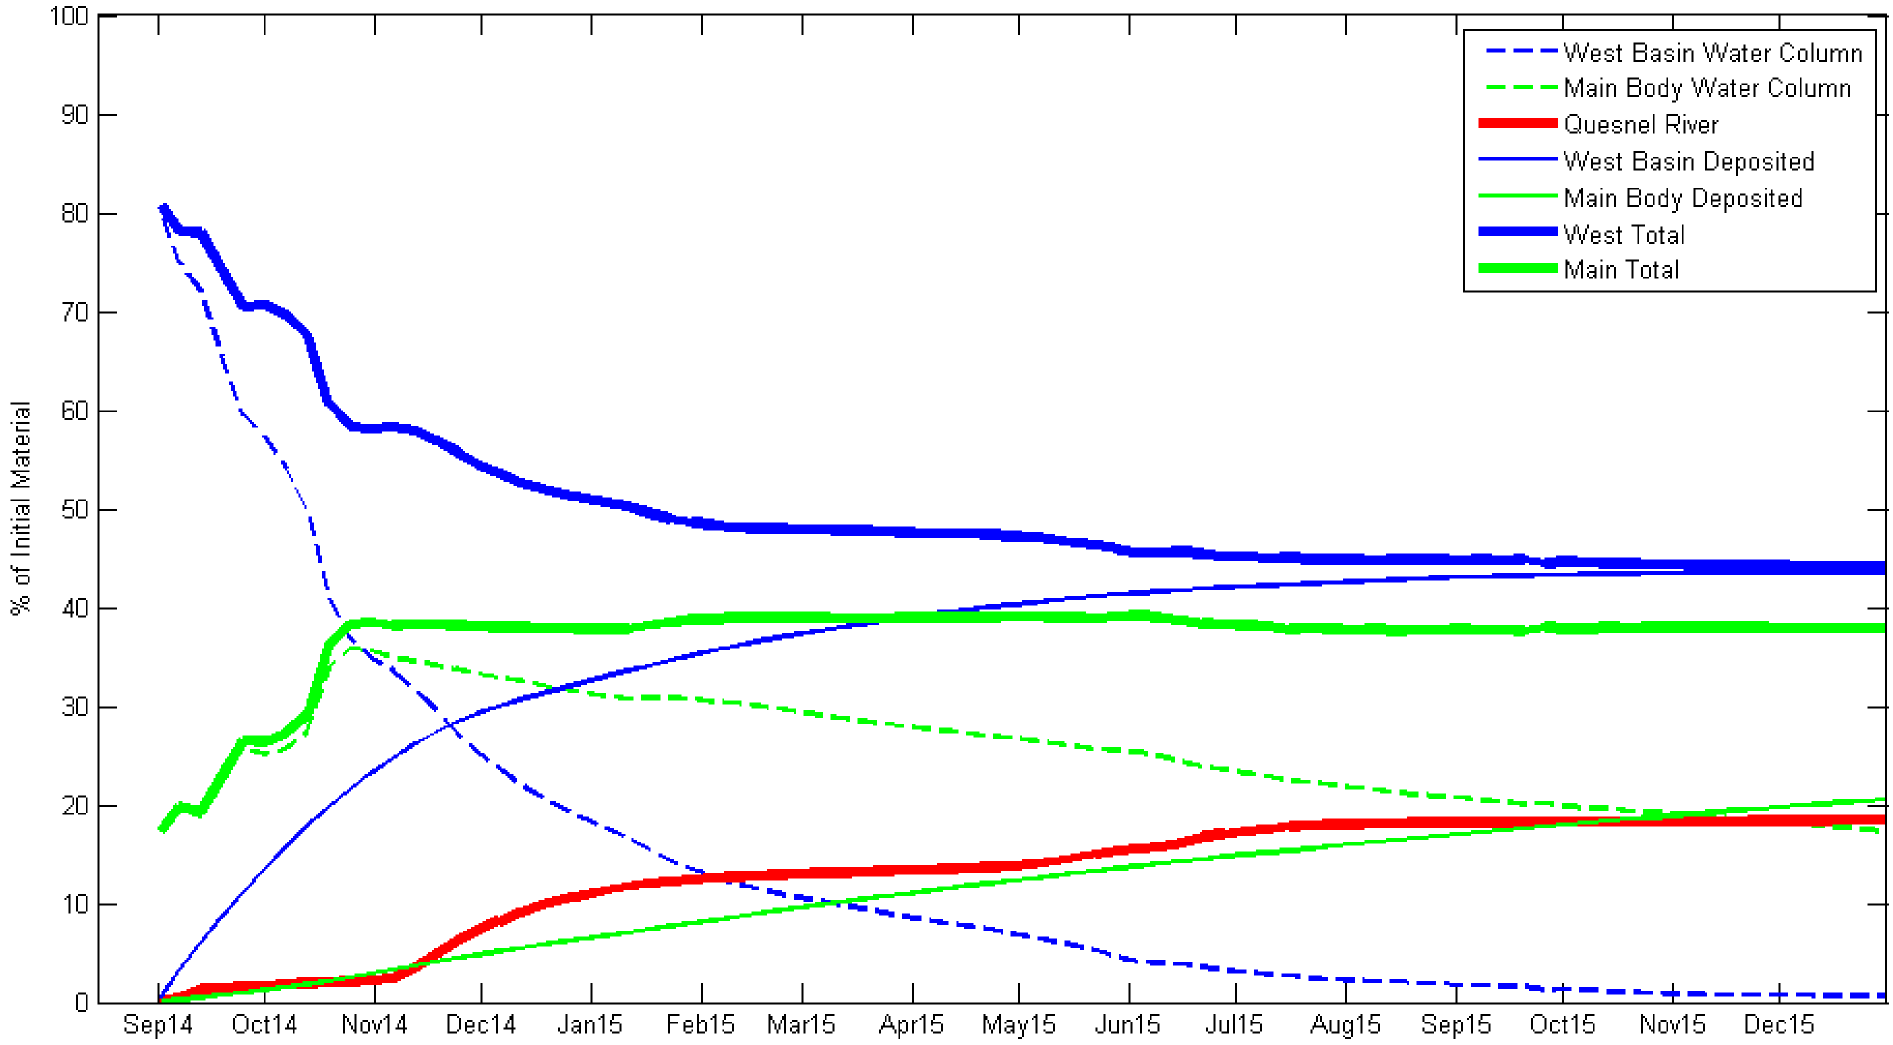
Figure 4.11



NOTES

The line plots show the relative distribution of material with time, as a percentage of the intial modelled suspended material.

The model's initial condition was generated by distributing 41.8 x 10^6 kg of suspended sediment throughout the West Basin and main body of Quesnel Lake based on observed turbidity casts between August 28 and September 6, 2014.

Approximately 80% of the suspended material was in the West Basin of the lake in the model's September 1 initial condition.

APPENDIX A

TETRA TECH EBA'S GENERAL CONDITIONS

GENERAL CONDITIONS

HYDROTECHNICAL

This report incorporates and is subject to these "General Conditions".

1.0 USE OF REPORTS AND OWNERSHIP

This report pertains to a specific site, a specific development, and a specific scope of work. The report may include plans, drawings, profiles and other supporting documents that collectively constitute the report (the "Report").

The Report is intended for the sole use of Tetra Tech EBA's Client (the "Client") as specifically identified in the Tetra Tech EBA Services Agreement or other Contract entered into with the Client (either of which is termed the "Services Agreement" herein). Tetra Tech EBA does not accept any responsibility for the accuracy of any of the data, analyses, recommendations or other contents of the Report when it is used or relied upon by any party other than the Client, unless authorized in writing by Tetra Tech EBA.

Any unauthorized use of the Report is at the sole risk of the user. Tetra Tech EBA accepts no responsibility whatsoever for any loss or damage where such loss or damage is alleged to be or, is in fact, caused by the unauthorized use of the Report.

Where Tetra Tech EBA has expressly authorized the use of the Report by a third party (an "Authorized Party"), consideration for such authorization is the Authorized Party's acceptance of these General Conditions as well as any limitations on liability contained in the Services Agreement with the Client (all of which is collectively termed the "Limitations on Liability"). The Authorized Party should carefully review both these General Conditions and the Services Agreement prior to making any use of the Report. Any use made of the Report by an Authorized Party constitutes the Authorized Party's express acceptance of, and agreement to, the Limitations on Liability.

The Report and any other form or type of data or documents generated by Tetra Tech EBA during the performance of the work are Tetra Tech EBA's professional work product and shall remain the copyright property of Tetra Tech EBA.

The Report is subject to copyright and shall not be reproduced either wholly or in part without the prior, written permission of Tetra Tech EBA. Additional copies of the Report, if required, may be obtained upon request.

2.0 ALTERNATIVE REPORT FORMAT

Where Tetra Tech EBA submits both electronic file and hard copy versions of the Report or any drawings or other project-related documents and deliverables (collectively termed Tetra Tech EBA's "Instruments of Professional Service"), only the signed and/or sealed versions shall be considered final. The original signed and/or sealed version archived by Tetra Tech EBA shall be deemed to be the original. Tetra Tech EBA will archive the original signed and/or sealed version for a maximum period of 10 years.

Both electronic file and hard copy versions of Tetra Tech EBA's Instruments of Professional Service shall not, under any circumstances, be altered by any party except Tetra Tech EBA. Tetra Tech EBA's Instruments of Professional Service will be used only and exactly as submitted by Tetra Tech EBA.

Electronic files submitted by Tetra Tech EBA have been prepared and submitted using specific software and hardware systems. Tetra Tech EBA makes no representation about the compatibility of these files with the Client's current or future software and hardware systems.

3.0 STANDARD OF CARE

Services performed by Tetra Tech EBA for the Report have been conducted in accordance with the Services Agreement, in a manner consistent with the level of skill ordinarily exercised by members of the profession currently practicing under similar conditions in the jurisdiction in which the services are provided. Professional judgment has been applied in developing the conclusions and/or recommendations provided in this Report. No warranty or guarantee, express or implied, is made concerning the test results, comments, recommendations, or any other portion of the Report.

If any error or omission is detected by the Client or an Authorized Party, the error or omission must be immediately brought to the attention of Tetra Tech EBA.

4.0 ENVIRONMENTAL AND REGULATORY ISSUES

Unless expressly agreed to in the Services Agreement, Tetra Tech EBA was not retained to investigate, address or consider, and has not investigated, addressed or considered any environmental or regulatory issues associated with the project.

5.0 DISCLOSURE OF INFORMATION BY CLIENT

The Client acknowledges that it has fully cooperated with Tetra Tech EBA with respect to the provision of all available information on the past, present, and proposed conditions on the site, including historical information respecting the use of the site. The Client further acknowledges that in order for Tetra Tech EBA to properly provide the services contracted for in the Services Agreement, Tetra Tech EBA has relied upon the Client with respect to both the full disclosure and accuracy of any such information.

6.0 INFORMATION PROVIDED TO TETRA TECH EBA BY OTHERS

During the performance of the work and the preparation of this Report, Tetra Tech EBA may have relied on information provided by persons other than the Client.

While Tetra Tech EBA endeavours to verify the accuracy of such information, Tetra Tech EBA accepts no responsibility for the accuracy or the reliability of such information even where inaccurate or unreliable information impacts any recommendations, design or other deliverables and causes the Client or an Authorized Party loss or damage.

7.0 GENERAL LIMITATIONS OF REPORT

This Report is based solely on the conditions present and the data available to Tetra Tech EBA at the time the Report was prepared.

The Client, and any Authorized Party, acknowledges that the Report is based on limited data and that the conclusions, opinions, and recommendations contained in the Report are the result of the application of professional judgment to such limited data.

The Report is not applicable to any other sites, nor should it be relied upon for types of development other than those to which it refers. Any variation from the site conditions present at or the development proposed as of the date of the Report requires a supplementary investigation and assessment.

It is incumbent upon the Client and any Authorized Party, to be knowledgeable of the level of risk that has been incorporated into the project design, in consideration of the level of the hydrotechnical information that was reasonably acquired to facilitate completion of the design.

The Client acknowledges that Tetra Tech EBA is neither qualified to, nor is it making, any recommendations with respect to the purchase, sale, investment or development of the property, the decisions on which are the sole responsibility of the Client.

8.0 JOB SITE SAFETY

Tetra Tech EBA is only responsible for the activities of its employees on the job site and was not and will not be responsible for the supervision of any other persons whatsoever. The presence of Tetra Tech EBA personnel on site shall not be construed in any way to relieve the Client or any other persons on site from their responsibility for job site safety.

1. Overview and Scope of Work

Tetra Tech was contracted by MPMC to conduct a geophysical survey in Quesnel Lake, British Columbia to map the bottom and water column to provide data to assist in determining the quantity and distribution of mine tailing material that had escaped from the Mount Polley tailings pond into the lake. The survey was performed between August 30 and September 6, 2014 using two vessels. The survey included the area around the material outflow near Hazeltine Point, northwest past Cedar Point Provincial Park, east to the area around Cariboo Island, with reconnaissance level survey extending further east. The primary goals of the survey work were to:

- Perform a multibeam bathymetry, side-scan sonar imagery and sub-bottom profiler survey of the project area to map lake floor bathymetry, areas of deposition and other surficial features of interest;
- perform acoustic imagery, conductivity, temperature and depth (CTD) and turbidity sensor measurements through the water column to map suspended sediment levels; and
- support bottom sampling to map the distribution of tailings deposition on the lake floor.

2. Equipment

Tetra Tech mobilized two survey launches to Lake Quesnel to conduct the geophysical investigation; the R/V Storm, a 21 foot aluminum jet boat, and the R/V Ugle Duckling, a 37 foot aluminum vessel. The larger vessel was equipped with an A frame and oceanographic winch to support towed sensor operations.

The primary equipment mobilized onto the survey vessels included a multibeam echosounder sonar, side-scan sonar, sub-bottom profiler, acoustic Doppler current profiler (ADCP), CTD/turbidity sensor systems, and towfish and vessel positioning equipment. These systems and the ancillary positioning and vessel attitude systems that were used to conduct the seabed mapping are listed in Table 1 and discussed in more detail in Section 3.

Table 1. Survey Equipment

Primary Equipment	Make/Model
Multibeam	RESON SeaBat 7125
Side-scan Sonar	EdgeTech 2000-DSS 100/600kHz chirp
Sub-bottom Profiler	EdgeTech 2000-DSS 2-16kHz chirp
ADCP	600 kHz Teledyne RDI Workhorse Sentinel

USBL	IXBLUE GAPS
Positioning Systems	Applanix POS/MV 320, Trimble SPS65x with OmniStar
Heading, and Motion Reference Systems	Applanix POS/MV 320, IXBLUE GAPS
CTD with Turbidity	Seabird 19 Plus, YSI CastAway
Grab Sampler	WILDCO Standard Ponar (or similar)

3. Field Operations

This section describes the vessels and equipment configurations for the two vessels mobilized to perform the geophysical survey.

3.1 R/V Storm

The R/V Storm was configured with a Teledyne RDI ADCP system to measure current velocities through the water column to aid in modeling sediment transport. The ADCP also provided water column acoustic imagery to aid in mapping suspended sediments. A combination CTD and turbidity sensor, which was lowered through the water column on a line, was deployed at a large number of locations to map the water column turbidity and associated water conditions (conductivity, temperature and depth). All data were geo-referenced using a differential global positioning system (DGPS) mounted on the vessel.

3.2 R/V Ugle Duckling

The R/V Ugle Duckling was configured with a RESON SeaBat 7125 multibeam sonar and an Applanix POS MV GPS aided inertial navigation system (INS) to provide vessel attitude, heading and position. Its equipment suite also included an IXBLUE Global Acoustic Positioning System (GAPS) ultra-short baseline (USBL) acoustic positioning system and GPS aided inertial navigation system used for tracking the towfish containing the side-scan imagery sonar and sub-bottom profiler. A Trimble SPS 650 series GPS provided corrections from the Trimble Marine Star system to the Applanix system to further improve positional accuracy. Mid-way through the survey, the GAPS INS, aided by the Trimble DGPS on the vessel, replaced the POS for primary vessel attitude corrections. Table 2 provides the offsets used for the HYPACK and HYSWEEP hardware setup and CARIS multibeam data processing software.

Table 2. R/V Ugle Duckling Sensor Offsets (in meters)

Sensor	Across (Starboard Positive)	Along (Forward Positive)	Vertical (Down Positive)
IXBLUE GAPS	1.800	-0.652	0.593

SeaBat 7125	-1.817	-0.625	0.821
Trimble SPS651	-1.805	-0.752	-2.619

The GAPS USBL also provided positioning for the towfish used to collect sidescan sonar imagery and sub-bottom profiler data. The Edgetech 2000-DSS towfish was configured with a dual frequency 100/600 kHz chirp side-scan system and a 2 to 16 kHz chirp sub-bottom profiler. The towfish was deployed from the vessel and dynamically flown approximately 10 to 20 meters above the bottom using the oceanographic winch mounted on the back deck of the vessel. During survey operations, the vessel also employed three CTD systems, one of which was configured with a turbidity sensor, to provide sound speed versus depth measurements needed for multibeam survey operations and to augment the water column monitoring being performed by the other vessel (R/V Storm).

3.3 Geodesy Settings

Horizontal (X, Y) positioning data for the project were collected in WGS84 Universal Transverse Mercator (UTM) Zone 10 North. Elevation data were collected CGVD28. The geodesy settings used for the project are presented in Table 3.

Table 3. Survey Geodesy Settings

Parameter	Setting
Horizontal Datum	WGS84
Vertical Datum (Geoid)	CGVD28 (HT2_0 geoid)
Coordinate System	UTM Zone 10N, Meters

4. Data Processing and Analysis

4.1 Geophysical Data Processing and Analysis

Tetra Tech's survey crew performed data processing in parallel with data collection on the vessel, to the extent possible, so that preliminary data products could be used to check data quality and confirm survey coverage. Final data products were prepared in Tetra Tech's offices in Seattle, WA and Vancouver, BC.

4.2 Bathymetry

The RESON SeaBat 7125 multibeam sonar was selected for this project to achieve maximum swath width and resolution given the project parameters. The support sensors used to measure vessel attitude (roll, pitch, and heave), position, and heading were selected to ensure that the associated accuracies were commensurate with the accuracy and resolution of the sonars.

Prior to field data collection, a standard patch test, also known as an installation calibration test, was carried out to calculate the angular offsets between the SeaBat 7125 and the vessel's motion reference units. The installation calibration process is used to derive the roll, pitch and yaw angular offsets between the multibeam sonar and the local reference frame defined by the motion reference unit. The installation calibration tests are also used to determine latency in the positioning equipment. The sonar, positioning system, and data collection computer are all time-synchronized to GPS Universal Coordinated Time (UTC), which should result in zero position latency. Results of the SeaBat 7125 patch test are displayed in Table 4.

Table 4. Multibeam Echosounder Patch Test Results

SeaBat 7125	Value
Roll	1.05 deg.
Pitch	2.35 deg.
Yaw	-1.85 deg.
Latency	0.0 sec.

Tetra Tech also performed a bar check to verify the depth reported by the sonar versus the depth of a target placed in the field of view of the sonar at a measured depth below the waterline. The HYPACK/HYSWEEP Bar Check Utility was used to collect and process the sonar data, correcting for system offsets and vessel attitude. The results are shown in Table 5.

Table 5. Multibeam Echosounder Bar Check Results

Parameter	Value
Bar Depth (m)	3.00
Sonar Measured Depth (m)	3.03
Difference (m)	0.03

The collected bathymetry data were processed with CARIS HIPS software to generate the XYZ soundings in the survey coordinate system and units. Data cleaning was also performed in CARIS HIPS 2D and 3D editing software to eliminate outliers induced by noise in the sensor system or the acoustic environment. A subsequent area-based cleaning, using the merged data from all the survey lines, was then conducted using the CARIS HIPS subset editing tool. Edited sounding data were used to create 2 meter-gridded Combined Uncertainty and Bathymetric

Estimator (CUBE) and uncertainty surfaces. Both types of surfaces were calculated by computing the uncertainty budgets for each sounding, based on beam geometry and the accuracies of the position system(s), motion sensor, and sonar devices, and applying a weight to each sounding based on an estimate of quality. ASCII XYZ files of the gridded BASE surfaces at 2 meter resolution were then exported out of CARIS and are provided in the deliverable digital data (Appendix B).

4.3 Side-scan Sonar

Additional data collected during the project included side-scan imagery sonar and sub-bottom profiler data from the towed EdgeTech 2000-DSS system. These data provided detailed images of features and textures on the lake bed, and information on the subsurface stratigraphy below the profiler.

Side-scan sonar imagery were acquired in proprietary EdgeTech format (JSF) using EdgeTech's Discover acquisition software and then imported into Chesapeake SonarWiz 5 for post-processing. Towfish position from the GAPS USBL was recorded directly into the raw data file and/or HYPACK for geo-referencing all raw data. The SonarWiz processing package was used to remove erroneous navigation points, apply gains and conduct other signal processing, bottom track the data to remove the water column, and prepare the sonar data for final export. The imagery was exported from SonarWiz as 0.25-meter resolution geotiffs and provided with the electronic deliverables in Appendix B and displayed on the charts provided in Appendix A.

4.4 Sub-bottom Profiling

Sub-bottom profiler data were also processed using the SonarWiz software. As with the side-scan sonar files, towfish position was acquired with the GAPS USBL and embedded in the raw data files acquired in the EdgeTech Discover and/or HYPACK programs. The files were recorded in the proprietary EdgeTech JSF format. The sub-bottom profile data were bottom-tracked and gains were applied where appropriate to distinguish different sediment layers on the lake bed where sediment layering was observed.

4.5 ADCP

ADCP data were collected and processed using the Teledyne-RDI WinRiver software. This system transmits a set of four beams at different angles from vertical and measures the Doppler shift vs time from each beam to derive current directions and magnitudes at various depths through the water column. It also tracks the return from the bottom to measure water depths and provides measurements of reflectivity vs depth in the water column that can be used to detect and delineate plumes of suspended sediment in the water column.

The current data at the surveyed positions within the lake and depths in the water column were used to help develop a hydrodynamic model of the portion of the lake where the tailing spill occurred. The water column imagery where used to provide snapshots and, through the use of multiple surveys over time, information on the dynamics of the suspended sediment plumes.

4.6 CTD & Turbidity

The turbidity sensor provided the most direct measurements of the amount of suspended sediment in the water column. Data from this sensor were compared to the conductivity and temperature measurements from the CTD to identify any correlation that would allow the use of the CTD, which has a much faster sample rate then the turbidity sensor, to be used to identify areas of suspended sediment.

The CTD and turbidity sensors could only provide periodic samples of the suspended sediments since the vessel had to move to a sample location, then an operator would lower the sensor system through the water column on a line, retrieve the system and download the data for that site to a computer. The ADCP could collect data and provide an image of any significant suspended sediment in the water column continuously, at rates up to several times a second, depending on water depth. By correlating the absolute measurements of the turbidity sensor to concurrent acoustic measurements with the ADCP, an estimate of a much higher density and volume of sediment plume mapping data than could be accomplished with the turbidity sensor and CTD alone, was obtained.

5. Summary of Findings

Maps showing the data collected from each of the sensor systems are provided in Appendix A.

5.1 Bathymetry and Side-scan Imagery

Figure 1 provides an overview of where the tailings spill occurred and shows the coverage of the bathymetry survey as a 3D surface, color coded for depth from blue (deep) to red (shallow). Sediment deltas and debris were visible in both the bathymetry and side-scan sonar imagery (Figures 1 and 2).

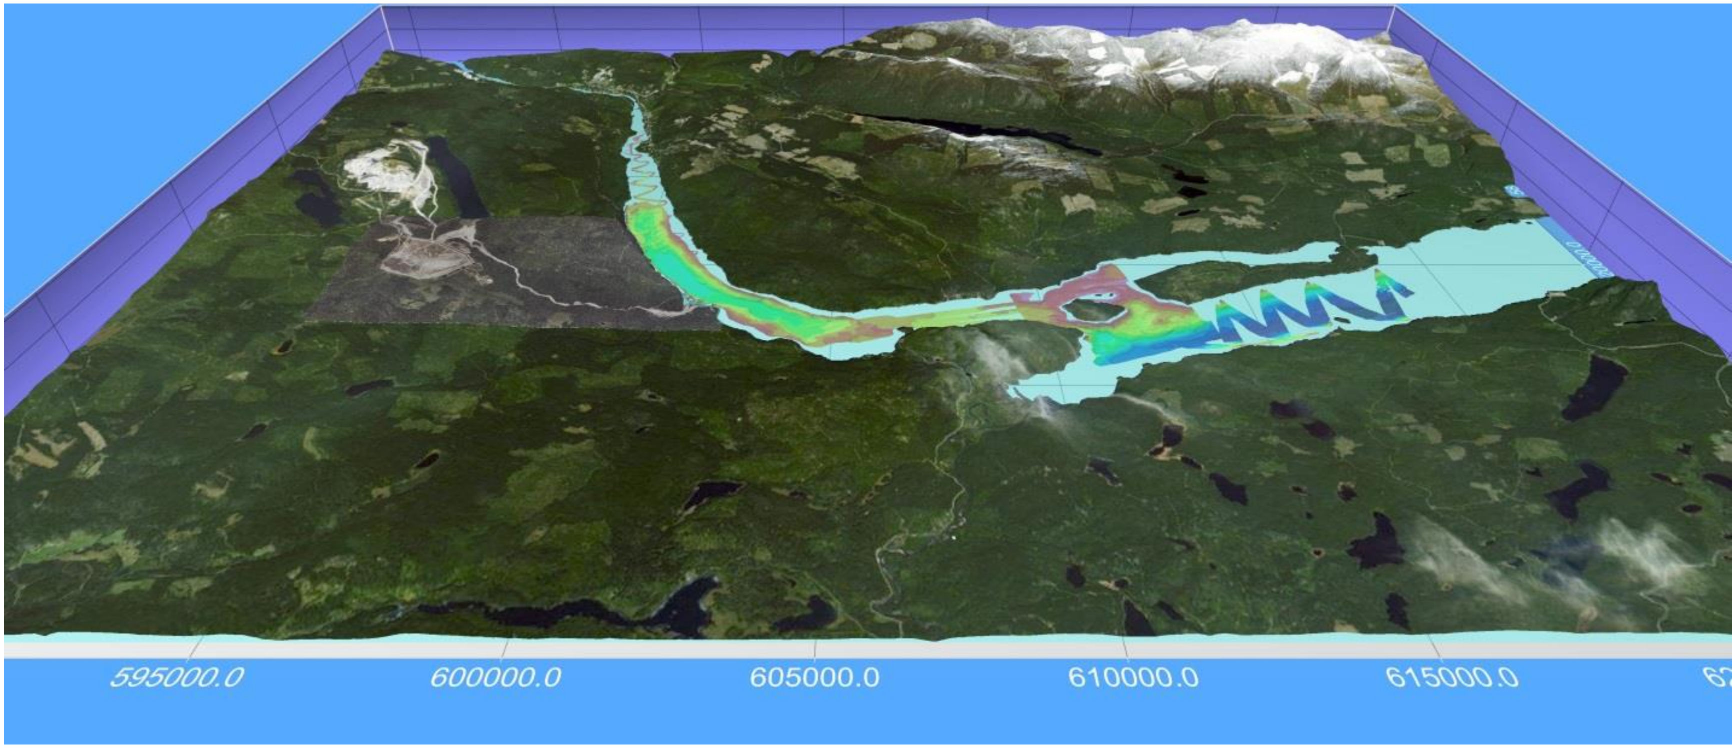

Figure 1 - Overview of Tailings Spill Area and Collected Bathymetry

Figure 2 shows the extent of side-scan sonar coverage near the tailings entrance point. The side-scan sonar towfish emits sound pulses perpendicular to the towfish heading in a narrow band to either side of the towfish. Some of the sound is absorbed by the lakebed and some scatters off the bottom in different directions. Sound that is scattered back towards the towfish receiver is called backscatter, and side-scan sonar images, as shown in Figure 2, represent this backscatter. The intensity of the acoustic backscatter is a function of several things, including:

- Angle of incidence of the acoustic wave front to the lakebed;
- Surface roughness;
- Impedance contrast across the solid/water interface (harder/firmer lakebed sediment or gravel are better reflectors than mud); and
- Topography (up slopes facing the towfish receiver are much better reflectors than down slopes due to a difference in incidence angle).

In general, high backscatter (or high reflectivity) areas show as dark shades while low reflectivity areas show as light shades. In general, areas of high backscatter/dark areas are associated with relatively coarser-grained sediments, hard substrate, steep slopes and rough bottom topography; while areas of low-backscatter/light with relatively finer-grained sediments, flat and smooth lakebed. In Figure 2, the dark areas are primarily the steep slopes along the edges of the lake, hard targets (likely large rocks, boulders and other debris that were washed into the lake with the tailings) found in the middle of the lake across from the tailings entry point, and where the tailings entered the lake on the south side. The lighter areas are primarily covered by fine-grained sediments.

5.2 Figure 2 - Side-scan Sonar Mosaic Adjacent to Tailings SpillSub-bottom Profiler

Penetration depth of the sub-bottom profiler provides information on sediment type and thickness. Areas that show distinct layering tend to be comprised of finer grained sediments such as fine sand, silt and clay; the sub-bottom profiler beam does not penetrate larger grained sediments such a coarse sand, gravel and cobble. The sub-bottom profiler data were reviewed with particular attention to the area around the outflow of the tailings material. Figure 3 shows the tracklines where sub-bottom profiler data were collected overlain on the bathymetry. Boxes show the locations of sub-bottom profiler data examples discussed in Section 5.3. The sub-bottom profiles show approximate depth (with 0 being at the water surface) on the vertical axis and along-track distance on the horizontal axis; with both axes in meters.

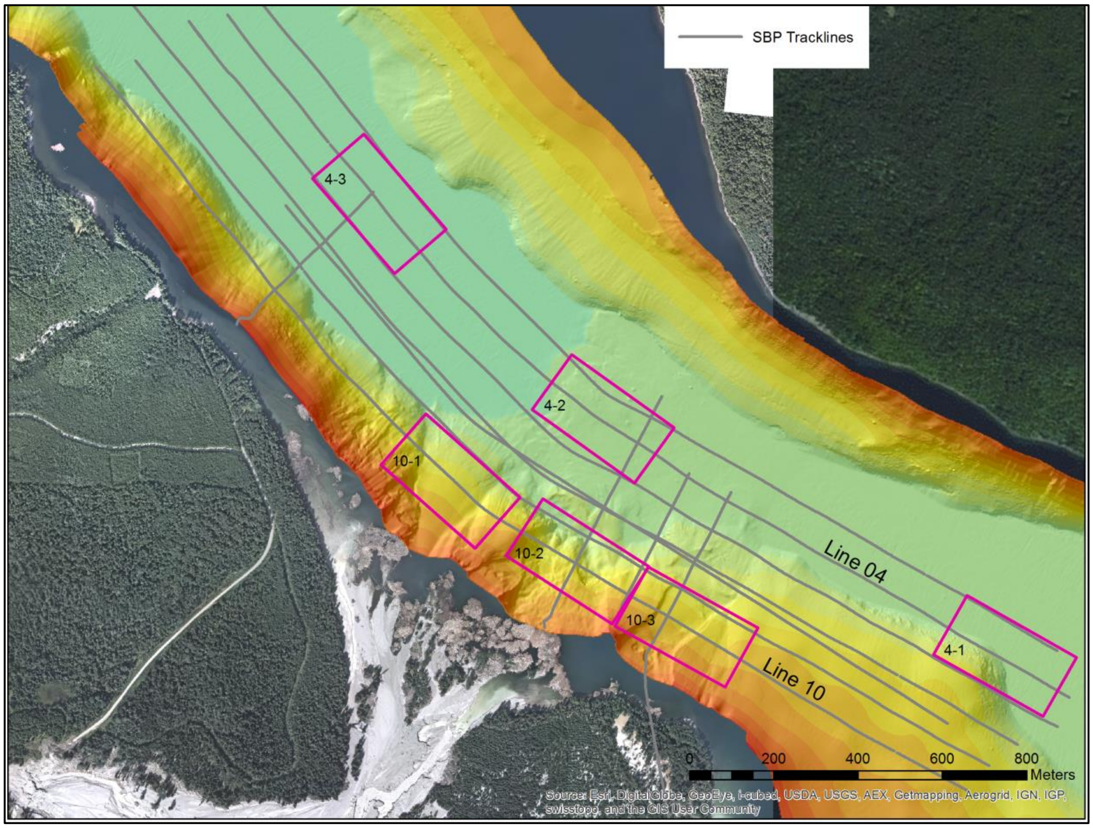

Figure 3 – Sub-bottom Profiler Tracklines; Boxes show locations of data examples discussed in Section 5-3.

5.3 Interpretation

If full coverage bathymetry data from before the spill were available, a comparison could be made with the survey performed by Tetra Tech to see where material had been deposited. Lacking a baseline survey of comparable coverage and quality to that performed after the spill, it was not possible to perform a highly accurate quantitative assessment of the volume and distribution of the tailings within the lake. However, review of the data by experienced geophysicists and hydrographic surveyors and correlation with the data derived from the sampling operations did provide some information on the distribution of the material.

Side-scan sonar data show that lakebed sediments appeared to be somewhat reflective west and east of the tailings entry site but appear to have slightly lower reflectivity in the vicinity of the tailings entry site. Numerous hard targets (primarily 1 to 2 m in size and up to 5 m) are scattered across the lakebed in this area and fan-shaped deposits of highly reflective, coarse-grained sediments were observed where water and tailings burst through the bank and into the lake (Figure 4).

Figure 4 – Hard Targets Scattered Across the Lakebed at the Tailings Entry Area

Sub-bottom profiler data indicate that lakebed sediments to the west and east of the tailings entry site are primarily fine-grained, particularly in the upper 5 to 10 m (refer to Figures 5 and 6).

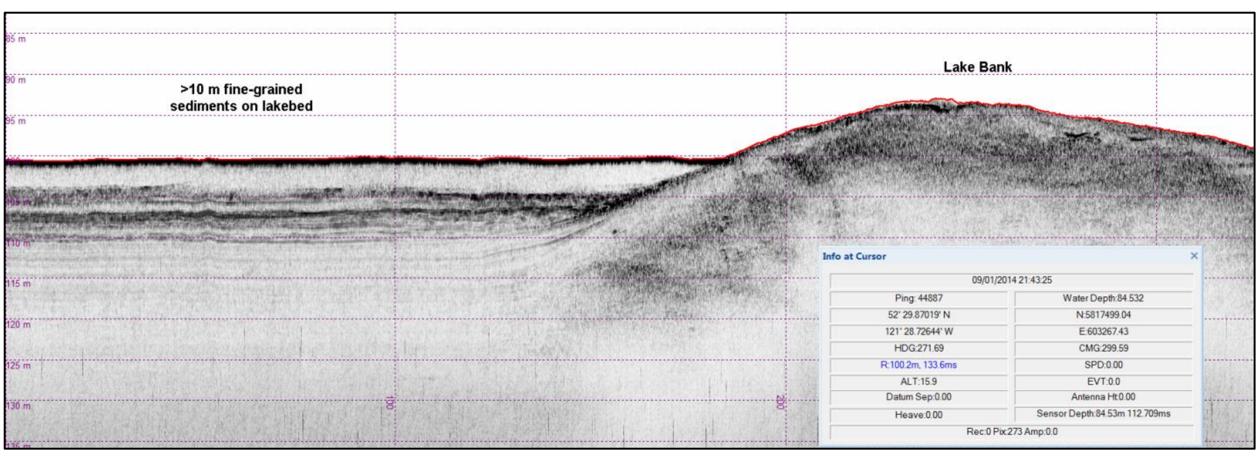

Figure 5 – Sub-bottom Profile East of the Tailings Deposit at Location 4-1 on Line 4 (refer to Figure 3).

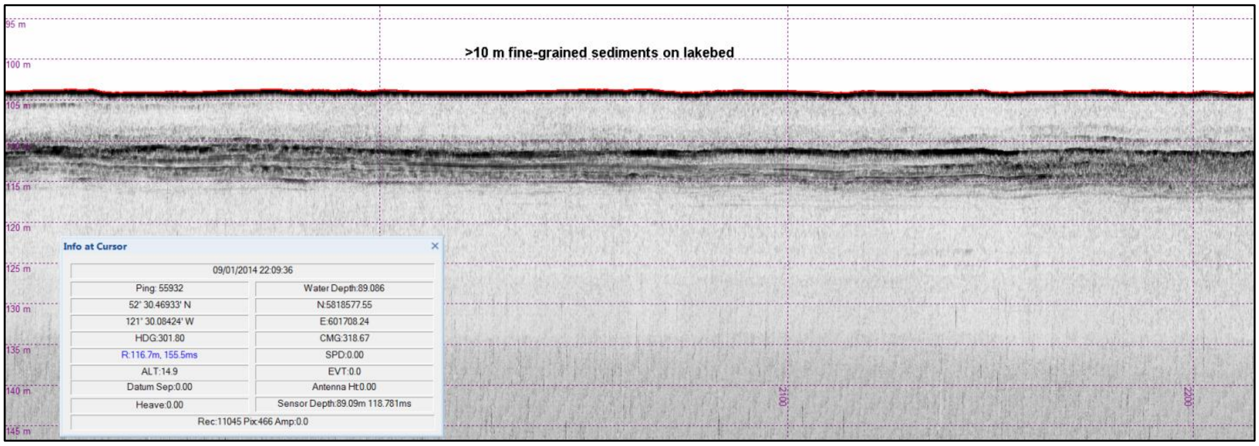

Figure 6 – Sub-bottom Profile Showing Fine-grained Sediments on the Lakebed at Location 4-3 (refer to Figure 3).

In the tailings entry area very little to no sub-surface penetration was observed (refer to Figure 7), indicating that sediments in this area are primarily coarse grained and likely include a large portion of the coarse-grained tailings that entered the lake. Because of the lack of sub-bottom penetration in the tailings deposition area an estimate of the volume of material that had been deposited (thickness of the coarse-grained material over pre-incident sediments) could not be made. In some places a very thin layer of fine-grained material over the coarse-grained material was observed on the lakebed surface and the relatively low-reflectivity of the side-scan data in this area suggests that a thin layer of fine grained material on the sediment surface is widespread.

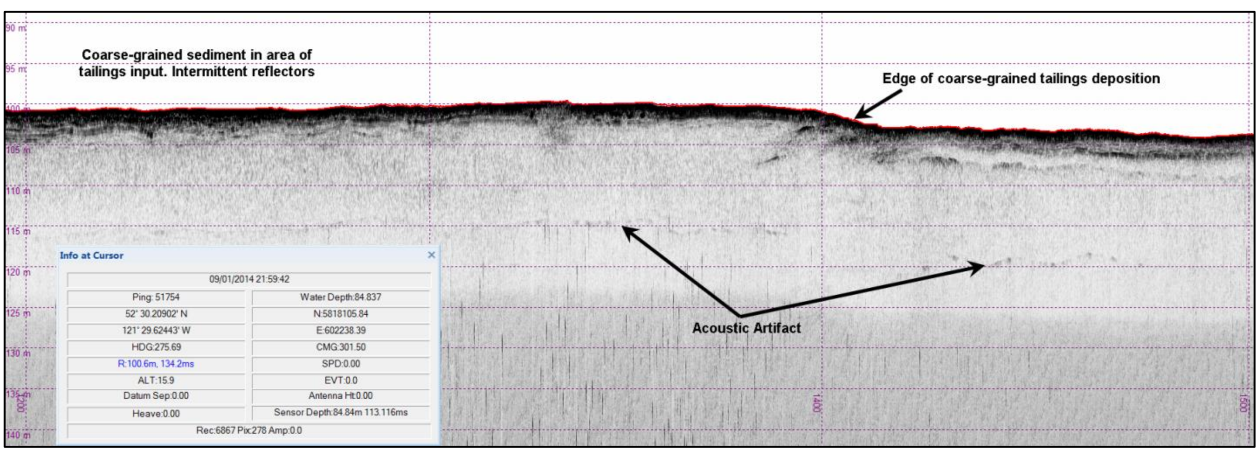

Figure 7 – Sub-bottom Profile Crossing the Tailings Deposition Area; location 4-2 on Line 4 (refer to Figure 3).

Three channels were mapped on the southern edge of the lake. The floor of the westernmost channel is relatively smooth and slightly mounded in the center (Figure 8) and sediments associated with this channel are distributed on the lakebed in a well-developed, not highly reflective, depositional fan (refer to Figure 2).

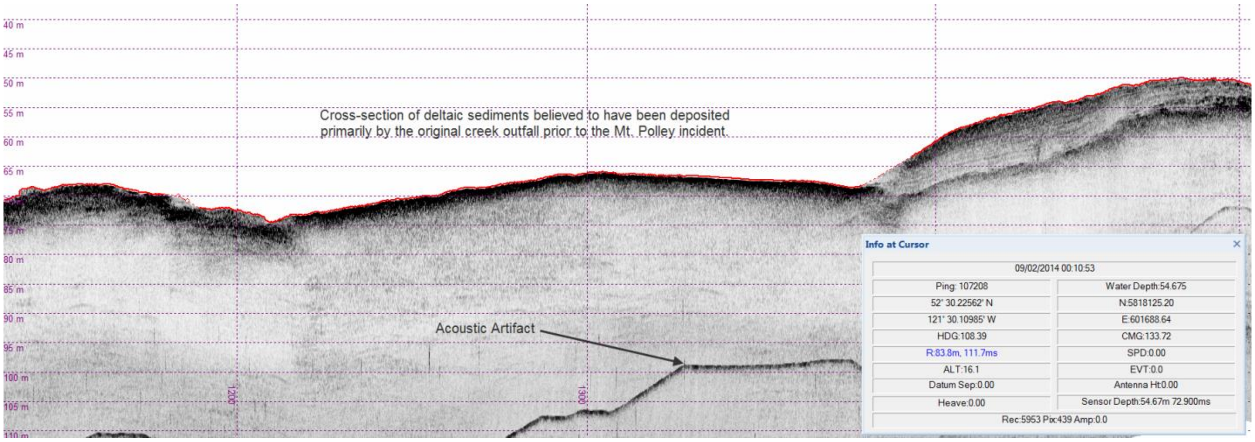

Figure 8 – Sub-bottom Profile Crossing the Location Where the Pre-Incident Creek Entered the Lake Prior to the Tailings Pond Breach; location 10-1 on Figure 3.

Pre-incident satellite imagery shows that Hazeltine Creek entered the lake at this location and the deltaic sediments are most likely associated with the creek (Figure 9).

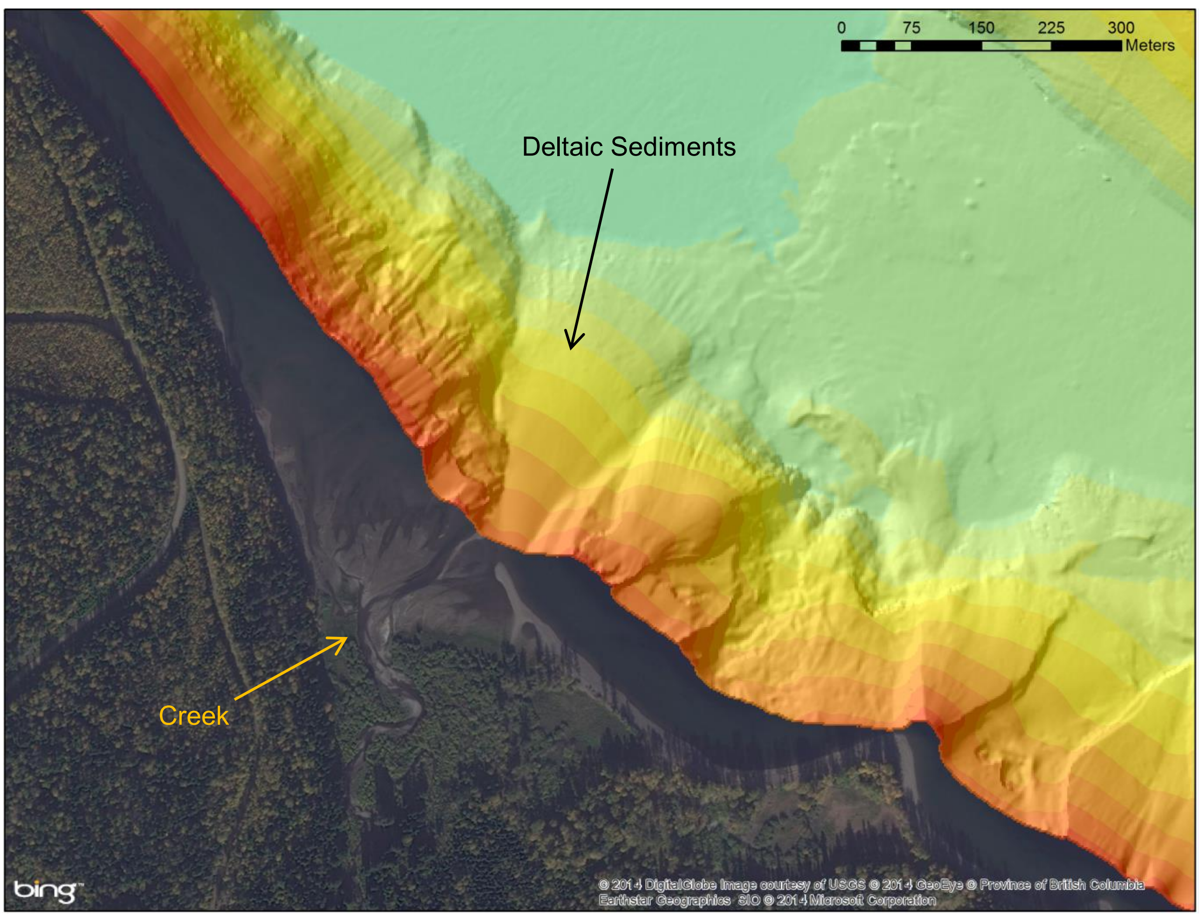

Figure 9 – Pre-Pond Breach Hazeltine Creek Flowing into Lake Quesnel with Associated Deltaic Deposit

To the east, two new channels have been carved out by the influx of material from the tailings pond breach and these appear to be the two primary pathways for tailings into the lake. The walls of these channels are steep and the floors are irregular and highly reflective (refer to Figures 10 and 11). Reflective material is evident in fan-shaped patterns across the lakebed and shoaling towards the northern shore of the lake opposite the channels suggests at least a meter of material was deposited on the lake bed in the vicinity of the tailings entry area.

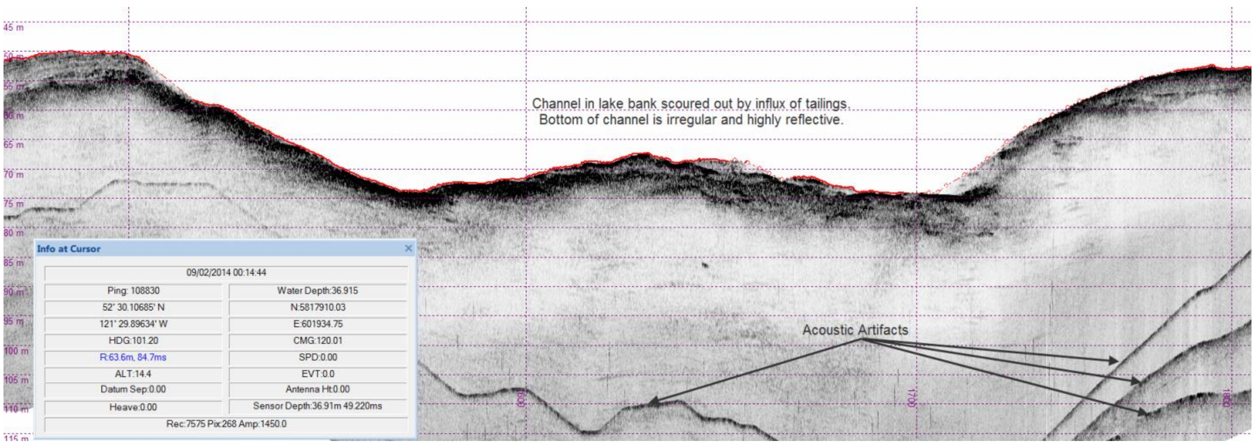

Figure 10 – Sub-bottom Profile Where the Profiler Crossed a Channel Formed by Influx of Material into the Lake; location 10-2 on Figure 3.

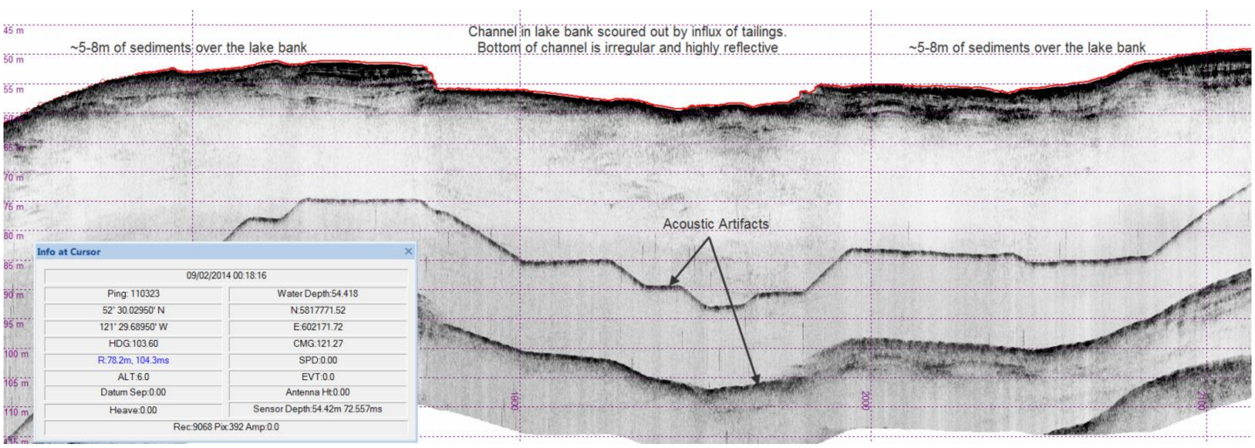

Figure 11 – Sub-bottom Profile Where the Profiler Crossed a Channel Formed by the Influx of Material into the Lake; location 10-3 on Figure 3.

The aerial photography collected after the tailings pond breach shown in Figure 12 and data from the various geophysical sensors indicated that a large portion of the tailings were deposited along the flow path to the lake and adjacent to the point where the material entered the lake through the two primary channels. The aerial photography also shows that the entry area into the lake extends across all three channels mapped in the bathymetry and therefore tailings material should not be expected to be contained by the channels. Once the tailings entered the lake, fine-grained material was likely entrained in the water column and slowly deposited further afield from the tailings deposition area. Grab samples collected along the lake confirm that the deposition of fines was much more widespread (Figure 12). Suspended sediment in the water column was observed during side-scan and sub-bottom profiler data collection but will be better mapped following analysis of the CTD casts.

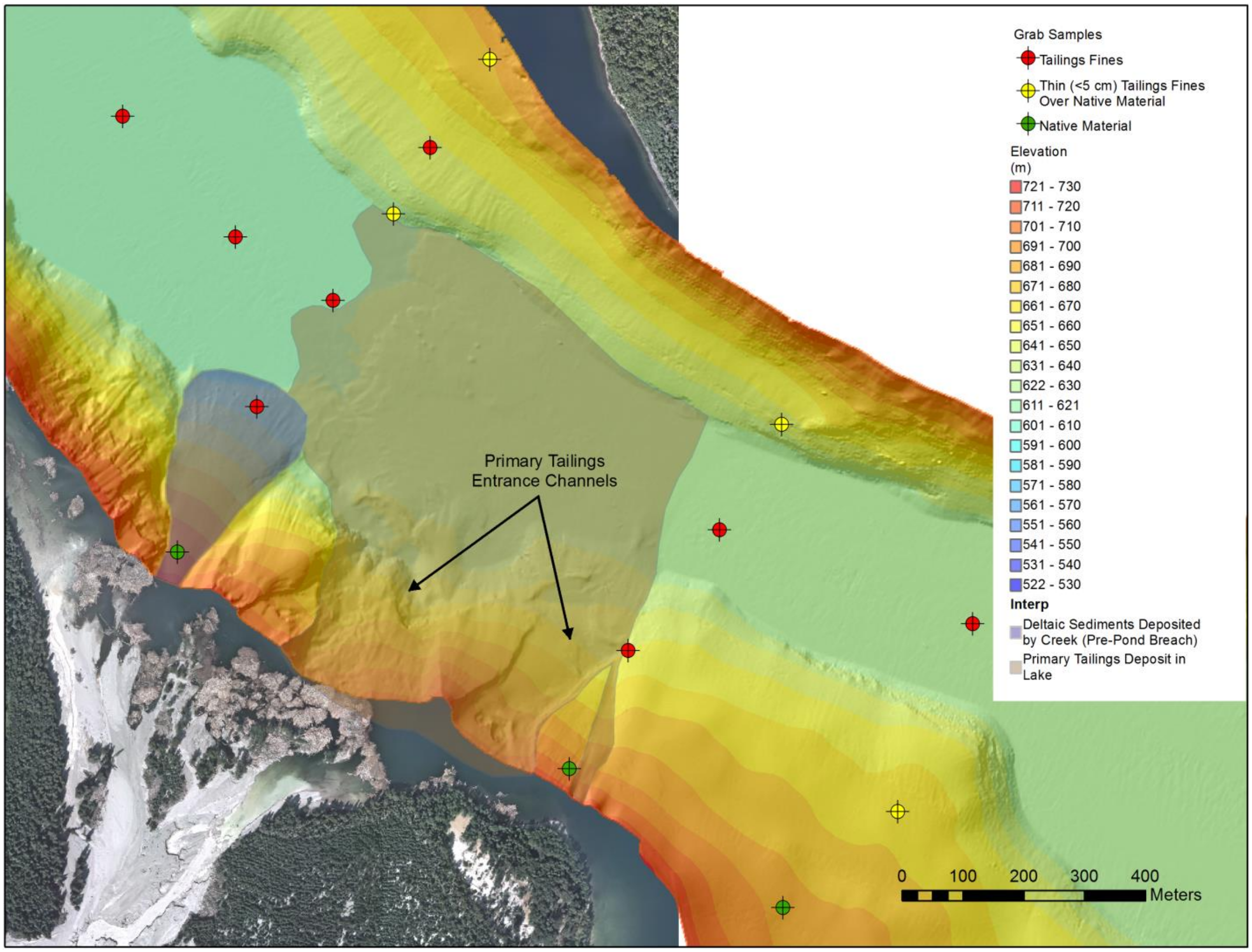

Figure 12 - Interpretation of Geophysical Data

6. Deliverables

Project deliverables include:

1. Summary Report – describes methods and equipment used to conduct the geophysical and summarizes results.
2. Charts (Appendix A)
   a. Chart 1 - Bathymetry map – Shaded relief bathymetry for Project area.
   b. Chart 2 - Side-scan sonar mosaic
3. Digital Files (Appendix B)
   a. XYZ grid of processed bathymetry
   b. Side-scan sonar mosaic

LIMITATIONS OF REPORT

This report and its contents are intended for the sole use of Imperial Metals Corporation and their agents. Tetra Tech EBA Inc. (Tetra Tech EBA) does not accept any responsibility for the accuracy of any of the data, the analysis, or the recommendations contained or referenced in the report when the report is used or relied upon by any Party other than Imperial Metals Corporation, or for any Project other than the proposed development at the subject site. Any such unauthorized use of this report is at the sole risk of the user. Use of this report is subject to the terms and conditions stated in Tetra Tech EBA's General Conditions are provided in Appendix B of this report.

1.0 INTRODUCTION AND BACKGROUND

Mount Polley mine is adjacent to Polley Lake, whose outflow forms Hazeltine Creek. About 8 km downstream of Polley Lake and Mount Polley mine, Hazeltine Creek enters the West Basin of Quesnel Lake. Quesnel Lake is a long, narrow fjord lake reaching from the Cariboo Mountains into the Interior Plateau of BC. Its average and maximum depths are 157 and 511 metres, respectively, making it the deepest fjord-type lake in the world (Laval et al, 2008). It has a surface area of about 266 km^2 and a volume of 42 km^3. With a mean annual outflow of 128 m^3/s through the Quesnel River, the lake has an average bulk residence time of 10 years. At the west end of the lake, a contraction and sill at Cariboo Island partially separates the main body of the lake from the West Basin, which represents 8.6% and 2.3% of Quesnel Lake's surface area and volume, respectively.

Subsequent to an August 4, 2014 breach of the Tailings Storage Facility (TSF) at the Mount Polley Mine and a debris flow along Hazeltine Creek, suspended particulate material entered Quesnel Lake. Tetra Tech EBA Inc. (Tetra Tech EBA) was retained by Imperial Metals Corporation to perform both field measurements and numerical analyses to develop a predictive model that would evaluate the fate of the suspended particulate material in Quesnel Lake and the turbidity resulting from that material.

1.1 Objectives

This report describes and discusses Tetra Tech EBA's field measurements, numerical analyses and hydrodynamic modelling. The objectives of this report are to:

1. Present and discuss the water column observations made by Tetra Tech EBA in 2014.
2. Develop and demonstrate an understanding of the lake's hydrodynamics.
3. Synthesize 1 and 2 to describe and predict the fate of the suspended material observed in the water column as a result of the TSF breach incident.

1.2 Lake Dynamics and Literature Review

In temperate lakes, the temperature of the surface water passes through 4°C, the temperature of maximum density, twice annually in a well-understood cycle. Summer warming produces a layer of warm, buoyant water at the surface of a lake. The temperature difference, and thus density difference, between this layer and the cooler water beneath creates a resistance to mixing which stabilizes or stratifies the lake. In the fall, the surface layer cools, reducing the density difference between surface and deeper waters, until the stratification is overcome by wind-induced mixing. This mixing typically involves the entire water column and is commonly referred to as "fall overturn." If the winter climate is sufficiently cold, cooling of the entire lake then continues until the surface is less than 4°C, at which point a reverse winter stratification appears: a cold, buoyant surface layer overlies a warmer (closer to 4°C) deep layer. In the spring, warming of the surface layer leads up to "spring overturn" when, again, the stratification is overcome by wind-induced mixing. Continued warming of the surface layer re-forms the summer stratification and completes the annual cycle. These mixing episodes have previously been observed in Quesnel Lake in December and April. See, for example, thermistor data presented in Potts (2004) and in Laval et al (2012).

In temperate lakes deeper than about 100-200 metres, the seasonal overturn cycle is complicated by high-pressure effects. The temperature of maximum density decreases with pressure, to approximately 3°C at a depth of 500 metres. This means that seasonal overturn events can only involve the upper 100-200 metres of the water column and deeper water is only renewed or displaced by subtle three-dimensional dynamics. For more discussion and numerous references, refer to Potts (2004) and Laval et al (2012). The main body of Quesnel Lake is subject to these effects. The West Basin of Quesnel Lake, however, with a maximum depth of just over 100 metres, follows the normal seasonal overturn cycle for temperate lakes.

The three largest inflows to the lake are east of the sill, whereas Quesnel River flows out of the western tip of the West Basin, meaning that nearly all of the hydraulic throughput of the lake must pass through the West Basin. Based on an average annual outflow of 128 m^3/s, the West Basin's average residence time is about 90 days.

The sill separating the West Basin and the main body of the lake has a maximum depth of 35 metres and forks around Cariboo Island (Figure 1.1). Internal waves, or seiches, between the upper and lower layers in the water column cause two-layer exchange flow over the sill following strong wind events. Using temperature measurements, Potts (2004) estimated the rate of exchange flow to be on the order of 1500 m^3/s, which dwarfs the river outflow by an order of magnitude. This exchange is frequent enough and large enough to fully replace the water in the cool, deeper layer in 6-8 weeks (Laval et al, 2008).

The key physical drivers of the lake are meteorological fluxes, wind, and rivers. Meteorological fluxes create the seasonal stratification and are dominated by shortwave and longwave radiation and evaporative heat transfer (Potts, 2004; Laval et al, 2012). Wind events are responsible for the seiche activity which can result in upwelling of cold water at the western tip of the lake and exchange flows across the sill (Laval et al, 2008) as well as episodic deep water renewal (Laval et al, 2012). Rivers also influence circulation and deep water renewal, but to a lesser degree (Laval et al, 2012).

1.3 2014 Tailings Dam Breach

The turbid water entering Quesnel Lake was denser than the lake water and therefore descended below the lake's surface, forming a submerged plume. After an initial turbulent inflow of unknown duration, the plume was constrained on the east by the sill separating the West Basin from the main lake body, and on the northwest by the shelf at the Quesnel River. Measurements throughout fall 2014 consistently located the plume extending vertically from a depth of approximately 30 metres to the lake bed, with occasional patchy outbreaks to the surface. The plume had elevated temperature, conductivity and suspended solids. The plume was mainly confined to the deep waters of the lake below the thermocline by density stratification caused by both the weight of the dissolved material and suspended sediment in the plume and the buoyancy of the warm surface layer persisting from the summer heating cycle of the lake. On occasion, the force of wind on the water surface can cause the interface between the upper and lower layers of a lake to tilt. This process brought the top of the turbid layer close to the surface periodically in the months following the event. Once the wind dies down, the event, known as an internal seiche, relaxes. Sufficient wind can also mix the two layers, either partially or completely. As the surface waters of the West Basin cool with the onset of fall, this stratification weakens and further wind energy resulted in complete mixing near the start of winter. The behaviour and fate of the turbid water in the West Basin was investigated using field methods and numerical modelling.

2.0 FIELD METHODS

Field observations in Quesnel Lake involved water column profiling by multiple organizations, bathymetric and geophysical data collection by Tetra Tech EBA, and sediment sampling carried out by Minnow, supported by Tetra Tech EBA's research vessels. This report presents data collected by Tetra Tech EBA during a field program from August 28 to September 6, 2014, where the research vessels R/V Storm and R/V Ugly Duckling were mobilized from Tetra Tech's Bothell, WA marine mapping group. Data collected by a joint MPMC/SNC water sampling and profiling program are also referenced. The water column profile data are described in detail in this report. Bathymetric, sidescan and sub-bottom profiling, and ADCP reflectivity measurements are discussed briefly in this report.

2.1 Water Column Profiling

Water column profiles are the primary method of gathering physical limnological data. Conductivity, temperature, and depth (CTD) casts measure three parameters essential for understanding the vertical density structure of a water body. Temperature is generally the dominant factor affecting circulation and water column stability in freshwater lakes. Section 1.2 above contains a discussion of the relevant temperature and density dynamics in Quesnel Lake. Electrical conductivity is the inverse of electrical resistance, and is correlated with the quantity of ionic material, usually salts and metals, dissolved in the water. Conductivity changes with temperature, so is generally normalized to a specific temperature and called specific conductivity. Depth is measured using a pressure sensor and integrating the water column density based on the temperature and conductivity measurements.

A key water column parameter for describing post-event Quesnel Lake is turbidity. Turbidity is an optical measure of water cloudiness – low-turbidity water would have high clarity. Turbidity is caused by a variety of factors, including sediment particles suspended in the water and biomass. The relationships between sediment concentration (by mass of suspended particles) and turbidity can be complex. Variability in particle size, shape, and mineralogy can result in different turbidity readings for the same concentration of material. Instrumentation is also a source of variability, as the measurement of light scattered off particles can be performed in different ways.

The BC Ministry of Environment (MoE) conducted CTD and turbidity (CTD+Tu) casts in the West Basin of Quesnel Lake on August 12 and 13, 2014 using a YSI 6600 sonde. The field sheets were hand-digitized and used for Tetra Tech EBA's initial analysis and modelling work. CTD and turbidity casts collected by MPMC using a YSI EXO2 sonde started to become available on August 19, with increasing coverage and frequency over time.

Tetra Tech EBA's research vessel R/V Storm began an intensive program of water column profiling on August 28, 2014, continuing through September 6, 2014. Tetra Tech EBA used a RBR Concerto CTD+Tu instrument on a hydrographic winch designed for rapid profiling.

Tetra Tech EBA staff joined the MPMC sampling program for two days in October 2014, and a key series of observations were made with both the YSI and RBR instruments on October 24, 2014. The instruments were compared in the field for quality control purposes, and a linear calibration coefficient was found between the two instruments. The Tetra Tech EBA measurements were then corrected to the MPMC measurements. Tetra Tech EBA reviewed the MPMC YSI calibration procedures during this visit and found them to be correct. There are differences in instrument design that likely explain the offset. Throughout this report the RBR turbidity readings are calibrated to match MPMC's instrumentation. Despite the natural and inherent uncertainty, turbidity provides the most useful rapid measurement of suspended material in the Quesnel Lake water column.

A quality-controlled up-cast and down-cast averaging procedure was used to post-process all Tetra Tech EBA CTD casts.

2.2 Multibeam Bathymetry

The primary equipment mobilized onto the survey vessels included a multibeam echosounder sonar, side-scan sonar, sub-bottom profiler, acoustic Doppler current profiler (ADCP), CTD/turbidity sensor systems, and towfish and vessel positioning equipment. These systems and the ancillary positioning systems that were used to conduct the seabed mapping are listed in Table 2.1 and discussed in more detail in future reporting.

Table 2.1. Survey Equipment

Primary Equipment	Make/Model
Multibeam	RESON SeaBat 7125
Side-scan Sonar	EdgeTech 2000-DSS 100/600kHz chirp
Sub-bottom Profiler	EdgeTech 2000-DSS 2-16kHz chirp
ADCP	Teledyne RDI Workhorse Sentinel 600 kHz
USBL	IXBLUE GAPS (Global acoustic positioning system; ultra-short baseline)
Positioning Systems	Applanix POS/MV 320, Trimble SPS65x with OmniStar
Heading, and Motion Reference Systems	Applanix POS/MV 320, IXBLUE GAPS
CTD with Turbidity	Seabird 19 Plus, YSI CastAway
Grab Sampler	WILDCO Standard Ponar (or similar)

The collected bathymetry data were processed with CARIS HIPS software to generate three dimensional maps in the survey coordinate system and units. Data quality control and assurance was also performed in CARIS HIPS 2D and 3D editing software to eliminate outliers typically produced by noise in the sensor system or the acoustic environment. Quality-controlled sounding data were used to create 2 meter-gridded Combined Uncertainty and Bathymetric Estimator (CUBE) and uncertainty surfaces. Both types of surfaces were calculated by computing the uncertainty budgets for each sounding, based on beam geometry and the accuracies of the position system(s), motion sensor, and sonar devices, and applying a weight to each sounding based on an estimate of quality. The bathymetric chart produced by the multibeam survey is reproduced in Figure 2.1.

2.3 Sidescan Sonar

Additional data collected during the project included side-scan imagery sonar and sub-bottom profiler data from the towed EdgeTech 2000-DSS system. This system, referred to as a towfish, is connected to the vessel by a cable and allows measurements to be made closer to the lake bottom. These data provided detailed images of features and textures on the lake bed, and information on the subsurface stratigraphy below the profiler.

Side-scan sonar imagery were acquired in proprietary EdgeTech format (JSF) using EdgeTech's Discover acquisition software and then imported into Chesapeake SonarWiz 5 for post-processing. Towfish position from the GAPS USBL was recorded directly into the raw data file and/or HYPACK for geo-referencing all raw data. The SonarWiz processing package was used to remove erroneous navigation points, apply gains and conduct other signal processing, bottom track the data to remove the water column, and prepare the sonar data for final export. The imagery was exported from SonarWiz as 0.25-meter resolution geotiffs and is displayed on the Figure 2.2.

2.4 Sub-Bottom Profiling

Sub-bottom profiler data were also processed using the SonarWiz software. As with the side-scan sonar files, towfish position was acquired with the GAPS USBL and embedded in the raw data files acquired in the EdgeTech Discover and/or HYPACK programs. The files were recorded in the proprietary EdgeTech JSF format. The sub-bottom profile data were bottom-tracked and gains were applied where appropriate to distinguish different sediment layers on the lake bed where sediment layering was observed.

2.5 Acoustic Doppler Current Meter (ADCP)

ADCP data were collected and processed using the Teledyne-RDI WinRiver software. The ADCP transmits a set of four beams at different angles from vertical and measures the Doppler shift vs time from each beam to derive current directions and magnitudes at closely-spaced depths through the water column. It also tracks the return signal from the bottom to measure water depths and provides measurements of reflectivity vs. depth in the water column that can be used to detect and delineate plumes of suspended sediment in the water column.

The current data at the surveyed positions within the lake and depths in the water column were used to help develop the hydrodynamic model. The water column imagery was used to provide snapshots and, through the use of multiple surveys over time, information on the dynamics of the suspended sediment plumes. While some reflectivity data did indicate the plume's presence in the West Basin of the lake, the frequency of the instrument did not measure the small grain sizes present in the plume very well. The CTD and turbidity data were more useful than the ADCP for plume tracking, and data processing effort was focused therefore on the CTD data.

2.6 Water and Sediment Sampling

MPMC conducted an extensive water column sampling program, discussed in detail in Golder (2015). Comparisons between observed and laboratory-derived conductivity is discussed in relationship to water density in Section 3.2 below. The relationships between turbidity and the laboratory Total Suspended Solids (TSS) measurements are discussed in Section 3 alongside estimates of the total mass of suspended material in Quesnel Lake.

Tetra Tech EBA's R/V Ugly Duckling supported Minnow Environmental staff in collecting grab samples from locations in Quesnel Lake. The grab sample results are discussed in Minnow (2015).

3.0 DATA ANALYSIS AND INTERPRETATION

3.1 Water Column Data

The digitized MoE CTD and turbidity profiles are the first full-depth measurements available in the post-event West Basin of Quesnel Lake. Two profiles, collected August 12 (blue) and August 13 (green) are shown in Figure 3.1. The turbidity profiles in Figure 3.1 show two distinct features, a nearly clear epilimnion (surface layer) above 35 metres and an increasingly turbid hypolimnion (deep layer) below 35 metres. The two profiles were collected on subsequent days approximately 3.5 km apart, and show similar patterns. The increasing turbidity with depth indicates settling of different grain sizes, for example with water from 40 to 80 metres depth being depleted of coarser particles such as silts, but retaining clay-sized particles in suspension.

The temperature profile in Figure 3.1 shows an atypical feature. As is typical of summer lakes, a thermocline exists from 0 to 20 metres with warmer, less dense water on top of cooler water. However, at the boundary between clear and turbid water at 35 metres, the profile is inverted with warmer water below cool. If temperature alone is considered in calculating density, the water column would be unstable and would immediately begin to mix and equalize. This turbid water consists of lake water mixed with water which originated in the shallow, warm tailing storage facility (TSF), and is kept below cooler water by the weight of suspended material. These issues of the effects of turbidity (representing suspended material), conductivity and temperature on water density are described further in Section 3.3 below.

The profile of specific conductivity shows a similar pattern, with a conductivity increase indicating increased dissolved solids below 35 metres.

The CTD and turbidity casts from Tetra Tech EBA's August 29 – September 5 field program are plotted by location in Figure 3.2 through 3.8, with data from different days plotted as lines of different colour. The figure locations start at the north end of the West Basin, near Cedar Point, and continue south and east past Plato Island. The lake was too rough for safe small boat work on September 3 so only some stations were visited with the larger vessel.

Figures 3.2, 3.3 and 3.4 have similar water column profiles at comparable depths. The thermocline was well-established on August 29, with a constant 18°C temperature in the top 15 metres, decreasing to a temperature minimum of 5°C at 25 metres, and increasing again within the turbid deep water to 7°C. Temperatures at depth were stable across the week, while temperatures at the surface indicate that wind mixing and surface cooling occurred during the September 3 storm event.

Figure 3.5 and 3.6 represent water on the west and east side of the Cariboo Island sill. This bathymetric feature is a barrier with maximum depth of approximately 35 metres, restricting the flow of bottom water in or out of the West Basin. Note the change for readability in the turbidity axis scale between Figures 3.5 and 3.6.

The casts near and beyond Plato Island (Figures 3.7 and 3.8) indicate the cold bottom waters typical of the main body of Quesnel Lake.

Quesnel Lake in fall 2014 can be considered as three distinct water masses defined by their location, temperature, and suspended sediment content, represented by turbidity. The coldest and largest water mass is found below the thermocline in the main body of the lake, seen on Figures 3.7 and 3.8 as 4°C water with turbidity near zero. The second water mass is warm surface water, also with low turbidity, seen on all of the above figures at depths less than 20 metres. The third water mass is the turbid bottom water in the West Basin, containing material and warm water introduced during the August 4 TSF breach. Quantifying the development, behaviour and fate of this turbid bottom water was the goal of the observations and modelling described in this report.

A layer of water between 20 and 35 metres in the West Basin contains cold and clear water that appears to have originated at a similar depth in the main lake body. Since the depth of the sill is 35 metres, there is an open path for exchange driven by either wind-induced currents or density differences. The mechanisms of exchange will be further examined in the modelling sections below, but it is inevitable that any transfer of water from the main lake body to the West Basin above the rate of the Quesnel River outflow must be matched by a return flow of water from the West Basin to the main lake body. Figures 3.6 and 3.7 show increased turbidity at depth, with a smooth and consistent spike near 20 metres and a less consistent signal near the bottom of each figure's casts.

Data collected on October 24, 2014 is presented in Figure 3.9. On this figure the casts in the West Basin are averaged into one profile, plotted in blue, and those in the main lake body are averaged into a profile plotted in green. The temperature inversion in the West Basin is much weaker, with a single thermocline at 35 metres below which is the turbid water mass, still near 7°C. Temperatures at the bottom are slightly higher than those at 50 metres depth. Surface water (above 15 metres) temperature and turbidity are the same in both basins, while in the main body of the lake a weak turbidity plume exists at depths between 20 and 50 metres. This figure represents the last synoptic (near-simultaneous) set of casts from which initial conditions were generated for the hydrodynamic model, and therefore the predictions of the plume's eventual fate depend on these data.

3.2 Sediment and Temperature Effects on Density

The temperature inversions in the West Basin described above indicate an anomalous density condition that must be explained by factors other than temperature because temperature alone would result in warmer water at the surface and cooler, denser water at depth. An increase of temperature in bottom water is not explained by normal physical limnological processes. The inflow of water that is warm but dense as a result of dissolved solids and suspended sediment provides a plausible explanation that fits with the event, safely assuming that water in the shallow Mount Polley TSF, in August, was relatively warm. Any material suspended in water results in an apparent change in the density of the water mass proportional to the volume percentage of material and its density relative to water. Dissolved material, like salt in the ocean, also increases the density of water and the results of analytical laboratory analysis of Quesnel Lake water are considered below.

MPMC has collected an extensive set of water samples from locations throughout Quesnel Lake, which were then analyzed for physical parameters such as hardness and nutrient content, as well as numerous other analytes. Using a limnology toolbox 'LIM' described in Pawlowicz (2008) and these laboratory results, a theoretical conductivity and density can be determined based on the concentration of each dissolved element or ion. The results of this comparison for 69 samples collected in the lake are shown in Figure 3.10. The x-axis in all the figures is the observed specific conductivity using a calibrated conductivity meter – the same reading that is made in each in-situ CTD cast.

The left-hand plot in Figure 3.10 indicates that the analytical determination of conductivity from laboratory data closely follows the observed value, though the predicted conductivity does appear to produce a slight underestimate compared with the measured. The LIM toolbox suggests that a match within 5% is considered quite good. The close correlation over a wide range of values indicates that specific conductivity, while not unique to any specific assemblage of material, is a candidate method, supplementing turbidity, for tracking water masses in Quesnel Lake over short periods of time, such as the fall and possibly winter of 2014. The centre plot shows the relationship between calculated density and observed conductivity, indicating that the amount of dissolved matter is sufficiently important to affect the behaviour of the water masses. The observed range of 0.04 kg/m^3 appears small, but represents the same density change as between 4°C and 6.25°C water. The right-hand plot indicates the corresponding salinity, in oceanographic salinity units, to the density and specific conductivity of the Quesnel Lake samples. As H3D is historically an oceanographic model, relating conductivity to salinity units allows use of the existing density subroutine. The differences in dissolved material content is important to the lake's hydrodynamics; however, this should not be correlated with any particular chemical parameter. Consideration of the composition of this water, including total and dissolved metals is addressed in greater detail in the Water Quality report.

3.3 Analytical and Modelled Suspended Sediment Mass

Once the above relationships between dissolved material and density in Quesnel Lake were generated, the effect of suspended material on density and stability of the observed temperature inversion in the West Basin was revisited. Figure 3.11 shows the results of a method to determine the minimum required suspended sediment mass based on water column stability. The left-hand plot shows seven quality-controlled and averaged temperature profiles collected between August 29 and September 5 by Tetra Tech EBA in the West Basin of Quesnel Lake. As described in Section 3.1, warmer water is observed below cold water, at depths greater than approximately 35 metres. The green lines on the right-hand plot show what the density of this water would be if only temperature were considered. It is not physically possible for the theoretical green density profile to exist over any length of time; heavier water floating on lighter water is not stable, and the bottom water would rise and mix, producing a more homogenous temperature and density profile.

The measurement of suspended material in the water column is Total Suspended Solids, or TSS. For modelling purposes we have assumed that TSS can be linearly related to turbidity. The red line shows density calculated using temperature as well as a turbidity to TSS relationship of 1 mg/L to 1.5 NTU (or TSS [mg/L] = 0.66 * Turbidity [NTU]). The density profile is still irregular. Increasing the sediment mass per turbidity unit can produce what appears to be a stable profile at lower depths, but the profile at 20-40 metres does not, in this observation, converge to a smoothly increasing density with depth.

The black lines on Figure 3.11 are calculated considering laboratory-derived dissolved solids with the conductivity/salinity/density relationship discussed above, and suspended solids with the same 1 mg/L: 1.5 NTU turbidity to TSS relationship. The calculated density increases over the thermocline, is nearly constant between 30 and 80 metres depth, and increases again below 80 metres where the turbidity increases faster than the temperature. This profile represents the minimum quantity of suspended solids required to maintain water column stability on the date of the observations, and from these relationships and the volume of the lake an estimate can be made of the total mass of suspended material present.

Figure 3.12 shows the mean, minimum and maximum observed turbidity profiles from the August 29-September 5 observations, and the inferred corresponding TSS profiles in the West Basin. The right-hand panel shows a hypsometric curve for the West Basin of Quesnel Lake. Lakes are wider at the surface than they are near the bottom; the area at depth zero is the surface area of the lake, the area at 110 metres depth is nearly zero as that is the maximum depth in the West Basin. Multiplying the TSS value at each depth interval by the area at that depth produces a profile of sediment mass, and integrating the profile gives a total.

The above calculations were repeated for the August 12 and 13 MoE observations, and for the October 24 observations discussed in Section 3.1. The results from this analysis are shown in Table 3.1, with the Lower Bound column representing the minimum mass required to explain the inverted temperature profile on each date. The mass is also presented as a percentage of the published loss of material from the TSF of 7.9 million cubic metres, using an assumed suspended sediment density of 2650 kg/m^3 to convert suspended mass to volume. The values decrease as time goes on, indicating either settling or export of the suspended material in the West Basin.

Table 3.1. Suspended Sediment Mass

	Lower Bound (kg)	% of Total Material	Model Initial Condition (kg)	% of Total Material
August 13	*28.8 - 37.8 x 10^6*	*0.15 – 0.20*	65.5 x 10^6	0.34
September 1	23.7 x 10^6	0.12	41.8 x 10^6	0.22
October 24	7.7 x 10^6	0.040	12.4 x 10^6	0.064

Initial laboratory analysis of Quesnel Lake water column samples provided input to the turbidity to TSS relationship used in the model. A more complete set of laboratory data is now available, discussed in detail in Golder (2015). Successful modelling of the turbidity and dynamics of Quesnel Lake requires an understanding, however approximate, of the density changes caused by both dissolved and suspended material.

Certain parameters necessary for modelling turbidity are summarized and discussed here. The total suspended solids, and the total dissolved solids excursion above background are plotted against observed turbidity in Figure 3.13. Simulation of lake dynamics is more sensitive to the relative properties of water masses, so subtracting the background TDS value to produce a TDS excursion was more useful given the initial limited number of samples available.

The scatter plots show great variability in the TSS to turbidity relationship, and there is valid technical reason, as noted below, to believe that the laboratory measured TSS is missing some fine-grained material. The TSS points in Figure 3.13 lie below the line representing the minimum TSS:turbidity relationship required for the stability of the observed temperature inversion.

The laboratory analytical technique for TSS measures material above a 1.5 micron grain size. According to detailed grain size distributions conducted by Minnow Environmental (Minnow 2015) the median grain size of samples within the turbid deep water is 1.0 microns. This material contributes to the bulk density of the water, but was not measured by the TSS laboratory method. Some colloidal sediment, or particulate material smaller than 0.45 microns, was likely measured as part of the total dissolved solids laboratory method. Adding the TDS excursion (difference from background) to the TSS values results in points more realistically above the line of minimum water column stability on Figure 3.13.

A variety of TSS:turbidity relationships were tested in the model based on earlier scatter plots of turbidity and dissolved and suspended solids. The production model runs were simulated using a TSS:turbidity relationship of 1 mg/L: 0.8 NTU (or TSS [mg/L] = 1.18 * Turbidity [NTU]), nearly double the material per turbidity unit than the minimum. The regression line representing the modelled TSS:turbidity relationship lies within the TSS + TDS excursion points on Figure 3.13, indicating that the semi-empirically derived model relationship is sufficiently reliable for prediction of turbidity relative to observations.

In summary, while there is uncertainty in the relationship between TSS and turbidity, as is the case in nearly all comparisons of these two different measures, there are minimum quantities of material necessary to maintain the inverted temperature profile in Quesnel Lake for the months which it persisted. Uncertainty resulting from analytical techniques was minimized by a series of model sensitivity tests, and subsequent laboratory data confirmed the assumptions regarding water mass composition and density that were necessary for predictions of turbidity dynamics, transport and fate.

4.0 MODELLING METHODS, DATA SOURCES AND ASSUMPTIONS

4.1 Model Description

A numerical model of Quesnel Lake was developed using H3D, a proprietary three-dimensional hydrodynamic model maintained by Tetra Tech EBA. The model is derived from GF8 (Stronach et al. 1993) developed for Fisheries and Oceans Canada. H3D has been successfully implemented on several extensive studies along the B.C. coast and inland waters.

A more comprehensive description of H3D is located in Appendix A, along with descriptions of the adjustable model parameters and their values for the Quesnel Lake simulations. One implementation relevant to lake and sill dynamics is the simulation of internal waves in Okanagan Lake, whose model validation figure is reproduced in Appendix B.

A curvilinear model grid was created for Quesnel Lake with higher resolution (70m cell size) in the West Basin of the lake (Figure 4.1). Model resolution indicates the smallest feature which can be resolved in the numerical simulation. Since the features of interest for this model are the large-scale behaviour of the lake, the horizontal resolution was chosen based on the minimum necessary to represent the sill at Cariboo Island. The vertical resolution was chosen to provide detailed coverage in the West Basin, which is approximately 100 metres deep, and less detail in the 500+ metre main body of the lake. The depth of the lake and resolution desired resulted in 90 vertical layers being used for the simulations.

Models must be calibrated based on available data, and subsequently validated with an independent dataset. The year 2003 was used for calibration due to the availability of thermistor data in the lake that year (Laval et al., 2008 & 2012). The calibrated model then was applied to simulate the fate of material in 2014 using the same numerical parameters as in 2003. The details of the model calibration are discussed in Section 5 below.

Initial conditions, meteorological inputs, and hydrologic inputs are described in the following sections. Figure 4.2 shows the locations of river inputs and calibration data.

4.2 Initial Conditions

The model must be started from an initial condition, which is a three-dimensional set of data representing all of the simulated parameters throughout the entire lake on a particular date or season. In the absence of a comprehensive survey, the model can be initialized with a small number of vertical profiles which are assumed to represent entire basins.

A good time to initialize a model of a dimictic lake is during the spring overturn where the water column is a constant temperature. The initial condition for temperature in the 2003 model was a constant 3.4°C throughout the lake based on historical thermistor data. No suspended sediment was simulated in 2003. The model was initiated from rest on April 15, 2003.

The 2014 models were initialized at three different times based on available data. One early model was initialized on August 12, using the post-event MoE casts to represent the West Basin and historical temperature profiles from the same month in the main lake body. A model was initialized on September 1, 2014 using casts from the Tetra Tech EBA field program which covered much of the western portion of the lake. A final model was initialized on October 24 using a series of casts from the joint Tetra Tech EBA / MPMC / SNC field visit.

4.3 Meteorological Inputs

Lake dynamics depend on local meteorology, with air temperature, sunlight and cloudiness, and humidity controlling the heat fluxes into and out of the lake, and wind providing energy for generating waves, currents, transfer across the air-water interface and vertical mixing in the water column. Wind is the most important driving force for lake hydrodynamics, transport and mixing processes. The wind field over Quesnel Lake is quite complex due to pronounced topography, as the orientation of the valley changes along the lake (Figure 4.2). The mountainous terrain which surrounds Quesnel Lake results in wind being steered along valley orientation, and either slowed, or funneled, depending on the regional wind directions. A number of current and historical meteorological stations, mapped in Figure 4.3, were investigated in order to understand wind patterns over the lake.

A representative comparison of wind speed and magnitude for some of these stations is presented in Figure 4.4 for the month of September 2003. The plot shows large variability in the wind field over the lake and region. Many of the wind stations were operational for short portions of the year or otherwise unreliable due to obstruction, poor placement, or data quality, such as forest fire stations which only reported wind quadrants for a portion of the summer.

In order to better understand wind patterns, we obtained a hindcast from the meteorological model MM5, which reproduces three-dimensional regional wind patterns. Since the 5 kilometre resolution of the MM5 hindcast was coarse compared to the valley topography, we downscaled the MM5 wind field over the lake using CALMET software which empirically represents the effects of topography. This meteorological model and downscaling system resulted in good performance in terms of event timing, however the wind velocities were much lower than coincident observations and it was not able to resolve the topography-following nature of the winds. Figure 4.5 demonstrates the discrepancies between observations and the MM5 prediction at Goose Spit and Niagara wind stations.

Over the course of successive model runs with varying wind assumptions, and based on previous work focused on the lake's heat balance (Potts, 2004), we came to conclusion that the most reliable source for wind, air temperature, cloud cover, and humidity data is the long-term time series available from the Williams Lake Airport (YWL). We therefore used this YWL wind time series, artificially rotated to be steered by valley topography, as in Figure 4.6. This wind steering assumption produced the best results during model calibration. Further changes were made in the wind steering assumption in response to greater than observed mixing behaviour in the West Basin. Model runs with reduced wind velocity in the West Basin of the lake produced improved results. This change, is physically based on the reduced width and wave-generating fetch in the West Basin that should result in less wind-driven vertical mixing than the open ocean mixing coefficients otherwise produced.

The remaining meteorological parameters are applied over Quesnel Lake directly from the YWL time series. Small time offsets likely exist between events at YWL and events at the lake, but are not significant to the weekly to seasonal time scales of concern.

4.4 Lake and River Hydrology

The Horsefly, Niagara and Mitchell Rivers are included in the model, with monthly average flows and temperatures taken from data available in Potts (2004).

The lake level is in balance between inflow and Quesnel River outflow. Inflows from the three rivers cause the lake level to increase. Higher lake levels cause increased flow out the Quesnel River, which is implemented in the model as a weir boundary condition. The WSC gauge at Likely and historical Quesnel River flows were combined to generate a simplified rating curve based on lake level. Year-to-year variability in inflow and outflow hydrology was not considered in the modelling. The average flows in the inflowing and Quesnel Rivers, as modelled, are shown in the top panel of Figure 4.7. The actual modelled Quesnel River flow is plotted against ten years of observed Quesnel River flows in Figure 4.7; the modelled line is time-shifted for comparison purposes. The modelled flows appear to be a good approximation of actual flows and are deemed sufficient for predicting lake and river processes.

5.0 MODEL VALIDATION

The hydrodynamic model of Quesnel Lake was validated in a variety of ways against available temperature observations in the lake:

- Temperature profile time series from 2003-2004 thermistor chains.
- Timing of fall overturn.
- Exchange flows over the sill.
- Temperature profiles from 2014 casts.
- Quesnel River temperatures.

Time series and profile comparisons provide visual evidence of model validity. In addition, each validation section presents the statistics for the skill of the numerical model in reproducing observations. The statistical methods used to measure model performance are based on calculation of the root-mean-square error (RMSE; Equation 1) and a comprehensive 'model skill' equation (Equation 2). RMSE is presented in the same units as the original data and represents the magnitude of the differences between observations and predictions over the model duration. Model skill (MS), as defined by Wilmott et al. (1981), is a dimensionless measure of the agreement between predicted and observed data, with a skill of one representing a perfect match.

Equation 1: Root-Mean-Square Error (RMSE)

$$\mathrm{RMSE} = \sqrt{\frac{1}{N}\sum_{N}|\mathrm{X_{Model}} - \mathrm{X_{Data}}|^2}$$

Equation 2: Model Skill (MS)

$$\mathrm{MS} = 1 - \frac{\sum|\mathrm{X_{Model}} - \mathrm{X_{Data}}|^2}{\sum(|\mathrm{X_{Model}} - \overline{\mathrm{X_{Data}}}| + |\mathrm{X_{Data}} - \overline{\mathrm{X_{Data}}}|)^2}$$

5.1 Temperature Profiles – 2003 Thermistor Data

Temperature profile time series were available from an observational program in 2003-2004 (Potts, 2004; Laval et al, 2012) in the West Basin and the main lake body (M2 and M8, respectively, in Figure 4.2). The M2 thermistor chain was anchored close to Hazeltine Creek, and represents temperatures in the West Basin. Digital data from M2 were available through the Institute of Ocean Sciences, Sidney, from July 31, 2002 through September 24, 2003. The M8 thermistor chain was anchored at the junction of the lake's three arms, and represents temperatures in the main body of the lake. Data from M8 were available through the University of British Columbia, from July 30, 2003 through June 22, 2004.

The modelled vertical profiles of temperature compared well with measurements at M2. A series of dated profiles are shown in panels on Figures 5.1 through 5.5, covering the period from April 15 to September 23, 2003. The overall RMSE on these profiles is 1.9°C and the model skill is 0.80. A review of these profile comparisons indicates that seasonal variation of temperature, the degree of stratification in the West Basin, and the location of thermocline were captured by the model.

Comparisons of daily modelled and observed temperature profiles at the M8 thermistor are shown in Figures 5.6 through 5.8. The model predicted the vertical variation of temperatures at this location with somewhat better overall accuracy than at the West Basin location, with an overall RMSE of 1.80°C and a model skill of 0.97.

A section through time, referred to here as a scroll plot, provides long-term information at all depths at a single location using colours to represent the quantity of interest. Figure 5.9 presents scroll plots of M2 (upper panel) and M8 (lower panel) temperatures from May 15 to September 24, 2003. Observed temperatures are shown with coloured dots, superimposed over the model-predicted temperatures on the same colour scale. If a dot is invisible it indicates a close match – nearly identical temperatures. The lake stays stratified from early June to the end of the plotted data in September.

Figure 5.10 presents the same plot, but with the time axis zoomed to highlight the upwelling events in the West Basin (M2; upper panel). Here, the thermocline fluctuations indicate wind-driven seiche activity, with distinct mixing, upwelling and downwelling effects. At the junction (M8; lower panel) the lake remains more stably stratified with less fluctuation of the thermocline. Since M8 is at or near the node of the first mode internal seiche, like a rider on the fulcrum of a seesaw, the observed temperatures show little sign of the fluctuations seen at M2. The model captured these seiche events reasonably well. The lower model skill at M2 is a result of the wind-driven seiche activity, with much of the difference between observations and predictions due to the lack of local wind data.

5.2 Fall Destratification in the West Basin

Fall cooling of the warm upper layer weakens the thermal stratification, ultimately leading to complete mixing of the water column. The model indicates that during mid-November the stratification disappears in the West Basin and water column turns homogenous (Figure 5.9). This is generally consistent with the observations at M2 in 2003 (Figure 5.11; reproduced from Laval et al, 2012), where the upper mixed layer gradually deepened through the water column from late September (20 m depth) to mid-November (98 m depth). Therefore, the mixing does not happen instantaneously as the common word "overturn" suggests. This gradual mixing inhibits the sudden resurfacing of deposited bottom sediment.

Note that the M2 data after September 24, 2003, were only available in graphical form, from Laval et al (2012), and therefore could not be displayed on Figure 5.9. This reduces the total length of record over which validation statistics are calculated, but does not change the conclusions regarding model skill.

5.3 Exchange Flows Over Sill

As mentioned in Section 1.2, the wind-induced seiche in Quesnel Lake often causes a two-layer exchange flow over the sill between the West Basin and the main lake body. This exchange flow has been has been captured in the model (Figure 5.12). During sustained winds from the west, warmer surface water leaves the West Basin and cold, deep water from the main lake body enters the West Basin. When the wind stops or changes direction, the warm surface water returns to the West Basin and the colder deep water returns to the main body of the lake. The magnitude of this flux over the sill was estimated by Potts (2004) using a heat conservation method based on the M2 thermistor representing heat content in the West Basin, and the M8 thermistor representing heat content in the main body of the lake. The root-mean-square (RMS) of the estimated flows was 1530 m^3/s. The RMS flows predicted by the model are about 1/3 lower: 960 m^3/s across the sill. This differs somewhat from the Potts (2004) estimates of 960 m^3/s; however, Potts' method, which relies on a single observation point to represent a large basin has considerable uncertainty. The heat conservation method may result in amplified peak flows which then overestimates RMS flow.

The difference of the fluxes entering and leaving the West Basin is equal to the Quesnel River flow which is shown for comparison in Figure 5.12. The instantaneous magnitude of the exchange flow is on the order of ten times greater than the river outflow, and it is proposed in Laval et al (2008) that it could take as little as 6-8 weeks for internal seiche processes to completely exchange the cool, deep West Basin water mass with water from the main lake body. The amount of deep water exchanged between the West Basin and the main body of the lake will be explored further in the modelled characterization of the 2014 event in Section 6 below.

5.4 Quesnel Lake Profiles - 2014 CTD Cast Data

Comparison of observed and modelled temperature profiles is an important method for validating a lake model. Various organizations began measuring water column properties in Quesnel Lake after the TSF breach. The earliest available data were from casts performed by the British Columbia Ministry of Environment (MoE) on August 13, 2014. Tetra Tech EBA collected data in a series of profiles throughout the lake during a field campaign from August 28 to September 6, 2014. MPMC field crews also conducted water column profiling, as discussed in Section 2.1, and a joint observations were conducted by MPMC and Tetra Tech EBA on October 24, 2014, including a comparison of the two different profiling instruments.

Tetra Tech EBA used the most recent data sets to initialize the Quesnel Lake model as they became available. Initial modelling efforts used only one MoE cast for the West Basin and historical data for the main body of the lake. The late-August Tetra Tech EBA field program yielded a large quantity of data suitable for generating initial conditions, and the October 24 field sampling included ten synoptic casts between Likely and Plato.

It is not straightforward to initialize a model of a large lake, as temperature profiles can vary from one part of the lake to another. Models can also drift over time, especially considering that the TSS:turbidity relationship was expected to change over the course of fall 2014. The latest set of synoptic casts, on October 24, was used to initialize the models predicting winter, and future, conditions in the lake. However, the earlier datasets provide a useful validation tool. Two models were run, one with initial conditions from August 13 MoE casts, and another initialized with data from Tetra Tech EBA's September 1 field observations. The August initialization assumed a single MoE cast was representative of the entire West Basin, and that the remainder of Quesnel Lake had a temperature profile identical to an observation in August 2003.

The predicted temperature profiles from the model initialized on August 13 are compared with September 1 and October 24 CTD observations near Hazeltine in Figures 5.13 and 5.14. Figure 5.13 shows scroll plots of modelled temperature and turbidity at a station offshore of Hazeltine Creek. Data from CTD and turbidity casts are shown as superimposed circles; a circle which blends into the background indicates good agreement between model and observation. The surface and bottom temperatures match the observations well in both September and October. The turbidity scroll plot shows qualitative agreement in surface turbidity, but little was known regarding the composition of bottom water when this model was initialized so the bottom predictions diverge from observations.

Figure 5.14 shows line plot comparisons of specific CTD casts and model profiles at the exact time of the observation. The model has some difficulty simulating the lower-temperature water between 20 and 30 metres depth in September, although the model does reproduce the presence of warmer water below cooler water. The October profile is well-matched at the surface and bottom, with the observations showing a somewhat sharper thermocline than modelled.

The Tetra Tech EBA observations in late August and early September were used to improve the model's initial conditions, and a new simulation was started from this date. Casts from a number of consecutive days were averaged to produce a three-dimensional dataset of temperature and suspended sediment. The predictions from the model initialized September 1 are compared with October 24 observations in Figures 5.15 and 5.16. The model does better at reproducing the cool intermediate water at 20 to 40 metres depth, and the match to the October 24 profile is accurate.

Both models predict the future temperature profiles well, with surface and bottom temperatures within 0.6°C of observations and the thermocline depth matched within observation variability. Furthermore, the August initial condition appears adequate with respect to temperature, as the predicted temperatures during the months of September and October are very similar to the more accurate initial conditions of September 1.

5.5 Quesnel River Temperature – 2014 Sonde Data

A validation of the model's predicted Quesnel River temperature is shown in Figure 5.17 for the August 12 initial conditions and Figure 5.18 for the September 1 initial conditions. There are two features to the comparison – the seasonal cooling of the lake's surface waters and therefore Quesnel River outflow, and the event-scale changes in temperature due to upwelling of bottom water. Both initial conditions resulted in a model that accurately reproduced the temperature dips on August 22, September 5 and September 12, with small temporal offsets likely due to the uncertainty in wind and meteorology over the lake compared with YWL. The wind speeds in the West Basin and the air temperature are plotted in the lower panels on both figures. The upwelling events correspond to winds from the west, which push warm surface water out of the West Basin and cause cold water to rise to the surface to replace it.

The August model (Figure 5.17) diverges somewhat from the observed temperature during September, but the accurate fit otherwise supports the assumption that one profile can represent an entire basin. The model skill for the August temperature comparison is 0.99 and the RMS error is 0.93 °C. The September 1 initial condition appears to have started somewhat 'cool' near the surface, likely due to the averaging of multiple days of casts over the entire Tetra Tech EBA field program, some of which were after the September 3 storm event that cooled the lake surface. Despite this early inaccuracy, the total heat content of the lake appears better represented after the first two weeks of the model run, converging well to the observed river temperature from September 13 to the end of the plot. The model skill for the September comparison is 0.99 and the RMS error is 1.02 °C.

The prediction of observed river temperatures within 1 °C throughout the fall of 2014, including a 10 °C change over a four day upwelling event, indicates that the model is skillfully reproducing the physics of the lake. Further adjustment of model parameters cannot produce a better result without a more complete understanding of over-lake meteorology.

6.0 MODEL RESULTS – 2014 EVENT TURBIDITY PLUME

The Quesnel Lake hydrodynamic model, validated against 2003 thermistor data, 2014 river temperature data, and regular CTD casts throughout fall 2014, was run with initial conditions based on both the September 1 and October 24 profiles (described in Section 3.1) to describe the long-term fate of whatever suspended material remained in the water column in the months after the breach event. Historical meteorological data from YWL was used for all models up to a mid-February 2015 reporting cutoff, after which point winds from another year (2010) were substituted.

The models initialized on September 1 are used to discuss fluxes of suspended material between the river, West Basin, and main body of the lake. The September 1 model starts with 41.8 x10^6 kg of suspended sediment (0.22% of estimated total sediment loss from the TSF) distributed throughout the West Basin and main body of the lake based on observed turbidity.

The October 24 profiles represent the last synoptic, or near-real-time, set of turbidity data throughout the West Basin and the main body of the lake up to Plato Island. The October 24 model starts with 12.4 x10^6 kg of suspended sediment (0.064% of estimated total sediment input) distributed throughout the lake. This model is the basis for over-winter and future 2015 turbidity predictions in the Quesnel River and throughout Quesnel Lake.

There exists considerable uncertainty about the total quantity of material suspended in the lake, and its grain size distribution and settling rate. The suspended material in both models is represented as a 2-micron clay which would sink 10 metres in approximately 40 days in the absence of vertical mixing energy. Sensitivity tests indicate that the behaviour of the modelled lake is similar once a certain minimum quantity of suspended sediment is included.

6.1 Temperature and Turbidity Sections

A series of maps and sections present the initial and modelled distribution of turbidity in the West Basin of Quesnel Lake. The model was initialized on October 24, 2014 and run to the end of 2015. All maps show the turbidity in the surface layer of the model. The colour scale represents turbidity and is constant across the six maps and sections. Temperature is contoured as lines at 1 °C intervals. The map and section are both cut off at the same location somewhat east of Plato Island to better show detail in the West Basin and Cariboo Island region.

- Figure 6.1 – October 25, 2014. The model's initial condition based on ten casts on October 24, 2014; the model was initialized at the subsequent midnight. Conditions were calm during observations and the thermocline is at a constant depth of 25-30 m. Turbidity gradually increases with depth in the West Basin to a maximum near 50 NTU, although the colour scale cuts off at a lower value.

- Figure 6.2 – October 31, 2014. Approximately a week after model initialization, a wind event from the southeast deepens the thermocline near Likely, pushing turbid bottom water up and over the sill. The thermocline deepens in the main lake body as not all of the pooling water can fit into the West Basin.

- Figure 6.3 – November 10, 2014. Winds reverse, moving surface waters away from Likely and drawing turbid water closer to the surface. Some mixing may be occurring near Cariboo Island as surface water 'deepens' to cover the entire water column. Stratification is weaker (fewer temperature contour lines) than previously.

- Figure 6.4 – November 30, 2014. There is no evidence of temperature stratification in the West Basin, and a split between turbid material at the bottom and material mixed to the surface near Likely. This is a snapshot in the middle of what is termed the fall overturn, or progression to complete mixing.

- Figure 6.5 – January 15, 2015. Reverse temperature stratification has set in, with surface waters cooler than the bottom water near 4 °C. Some residual turbidity is predicted in the bottom water, with clear upper water connected to the main body of the lake.
- Figure 6.6 – August 17, 2015. The model includes no additional turbidity fluxes, such as from Hazeltine Creek or other rivers, so any turbidity remaining is only due to the original event. The model predicts some residual turbidity below the thermocline. The surface turbidity is below 0.1 NTU where the colour scale on the section plot is cut off.

The model run described in the previous maps and sections is summarized below in scroll plots and time series of river turbidity, focussed on locations just offshore of Hazeltine Creek and just east of Cariboo Island.

6.2 Turbidity Time Series

The modelled turbidity regime from October 24, 2014 through the end of 2015 is summarized in Figures 6.7 and 6.8 for three locations of interest. The figures are identical in content except Figure 6.7 shows the data from October 2014 to March 2015 in finer detail and Figure 6.8 shows the entire year of 2015.

The modelled and observed turbidity in the Quesnel River outflow is plotted in the top panel of both figures. The observed turbidity data was obtained from MPMC and comes from two sources, a water quality sonde at site QUR-1 (black lines), and laboratory analyses of water samples from the same site (black points). The observations and model show turbidity starting to increase above background levels on November 10. The model generally tracks the observed turbidity, with two brief (4-8 day, ~5 NTU) overestimates in mid- and late November. There are short-term spikes in the turbidity sonde time series that are not replicated in either the model or the laboratory samples; these are therefore interpreted as instrument noise or malfunction.

A number of model sensitivity tests were conducted in an effort to best match observations. The model parameters adjusted include the ratio between vertical mixing of velocity and scalars, and a factor decreasing the wind speeds in the West Basin relative to the rest of the lake. The Quesnel River turbidity time series from these alternate models are shown as blue lines. It is possible, by adjusting these parameters, to change the time at which complete vertical mixing occurred in the West Basin. The best-matching model results used a vertical diffusivity / viscosity ratio of 0.5, somewhat larger than the 0.1 used in the 2003 validation. Numerical details on this and other model parameters are discussed in Appendix B. The 2003 model, when rerun with a 0.5 ratio, performed with acceptable, but slightly lesser model skill. The goal of using the same numerical parameters in the calibration, validation, and production model runs is valid, but there is also a physical basis for using a different number in the mixing parameterization in years with and without a sediment-driven density interface.

Previously-published Tetra Tech EBA model predictions of winter 2015 water quality are shown in light blue. These predictions were presented in an initial MPMC memo "Quesnel Lake Cloudiness at Lake Overturn" on November 14, 2014. These models were superseded once model calibration was complete and the volume of sediment in the October 23 initial condition was refined based on observations and laboratory water quality analyses.

A scroll plot of turbidity at QUL-66a is shown in the centre panel for Figures 6.7 and 6.8, with a style similar to Figure 5.15 but for the October 24 initial conditions. The bottom panel of both figures contains a scroll plot from QUL-79, just east of Cariboo Island. Both scroll plots show MPMC turbidity casts as coloured boxes corresponding to the model's turbidity scale.

The scroll plots show evidence of episodic fluxes of material from the West Basin to the main body of the lake. These occur during or after wind events as the interface between clear surface water and turbid deep water tilts.

The flux of material over the sill was calculated from model results, combining the transport of water over the sill (as in Figure 5.12) with a sediment concentrations to produce a comparison of the rates of transport. The flux of water and suspended material from the September 1 model initial condition through February 2015 is shown in Figure 6.9. The third panel shows episodic transport of material from the West Basin to the main body of the lake. A smaller amount of material can briefly flow back into the West Basin as the seiche reverses phase and therefore transport direction. For much of the fall, transport is dominated by seiche dynamics and the river concentration of material is nearly zero. After the fall overturn the river flux increases and the seiche-induced transport decreases. The transport of material out the Quesnel River peaks in November 2014, and then decreases as both river flow and concentration drop over the remainder of the winter.

Quesnel Lake can be coarsely characterized as having a ten-year residence time based on its volume and the flow of rivers. Similarly, the residence time of the West Basin is on the order of three months considering the same river flow and a smaller volume. The reduction in West Basin turbidity on the time scale of a single residence time cannot be explained by average residence time, and the exchange over the sill provides a stronger explanation. As noted in Laval et al. (2008), a single large seiche and upwelling event can exchange 50-60% of the West Basin's bottom water, and multiple such events can continue to dilute and exchange bottom water.

The fluxes of West Basin bottom water over the sill help to explain why river turbidity at overturn was not as high as initially expected. The modelled behaviour of the turbid bottom waters in the West Basin support the interpretation that the bulk of observed suspended material either settled or was transported, much diluted, to the main body of the lake over the fall of 2014.

7.0 CONCLUSION

Observations, analysis, and modelling of Quesnel Lake after the August 4 TSF breach indicate that the suspended material introduced by the debris flow persisted in the water column at depth in the West Basin of the lake for a number of months before mixing either with surface waters or with the main body of the lake.

A series of field observations by MPMC and Tetra Tech EBA staff tracked a water mass containing suspended material and water originating in the TSF. The water mass had a distinct signature of elevated temperature, conductivity, and turbidity. Density calculations based on these three parameters allowed a characterization of the minimum mass of material present, and informed the setup of a hydrodynamic model of the lake.

The hydrodynamic model H3D was implemented in Quesnel Lake and validated to an existing dataset of temperature in 2003. A series of models were then run in 2014 based on specific observations in an iterative modelling process. Uncertainties in the data required for modelling include sparse wind observations and the changing composition of the material suspended in the lake due to settling and exchange processes. The uncertainties are of low impact on predictions, demonstrated by the model's successful reproduction of events such as observed seiches, where internal responses to wind events brought material and cold water close to the surface at Likely. The long-term evolution of Quesnel River turbidity was also well-characterized by the model.

The model predicts that, barring new sources of material, minor (1-2 NTU) residual turbidity may be found in bottom waters in the remainder of 2015. MPMC is currently executing a program of turbidity observations, to monitor the recovery of the lake. Analysis of sediment flux indicates that residence time of material in the West Basin was reduced by exchange processes over the sill at Cariboo Island, and much of the suspended material mixed with the main body of the lake instead of being transported out the Quesnel River.

8.0 CLOSURE

We trust this report meets your present requirements. If you have any questions or comments, please contact the undersigned.

Tetra Tech EBA - VANC	May 2015			

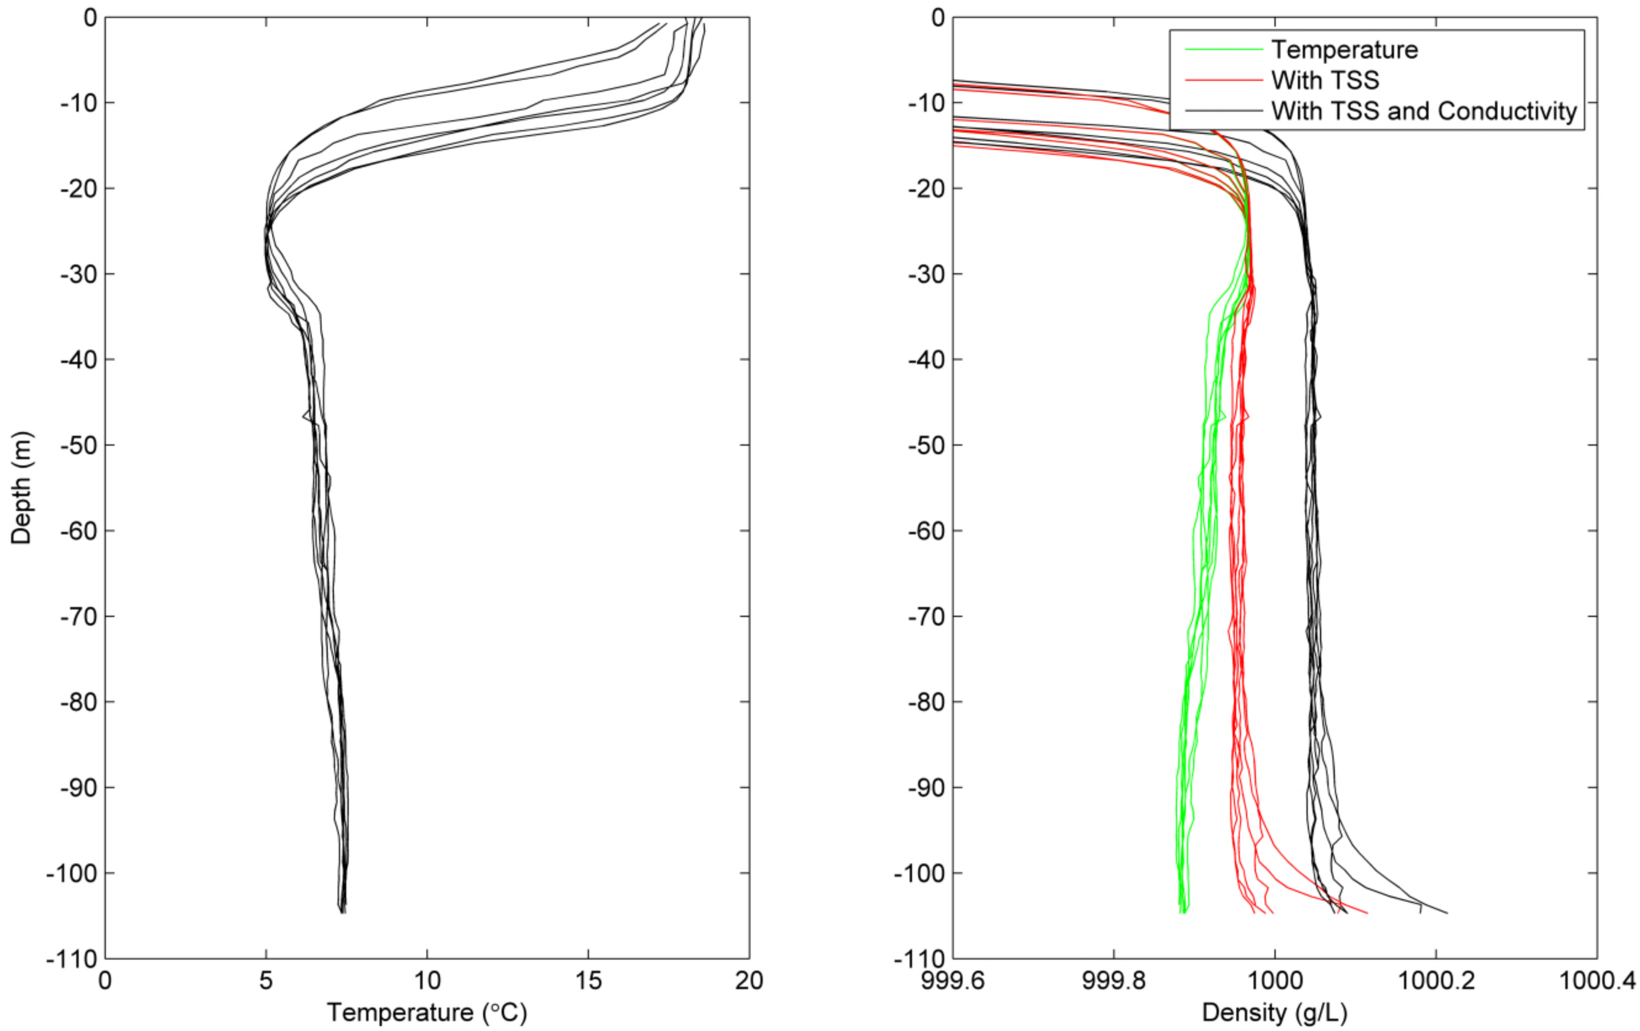
Figure 3.10



NOTES

A linear relationship between observed turbidity and actual total suspended solids (TSS) is assumed for this calculation.

The minimum Turbidity : TSS relationship required for water column stability was calculated as a ratio of 1 mg/L to 1.5 NTU based on casts in the West Basin between August 28 and September 1, 2014.

Turbidity units were corrected to match YSI calibration

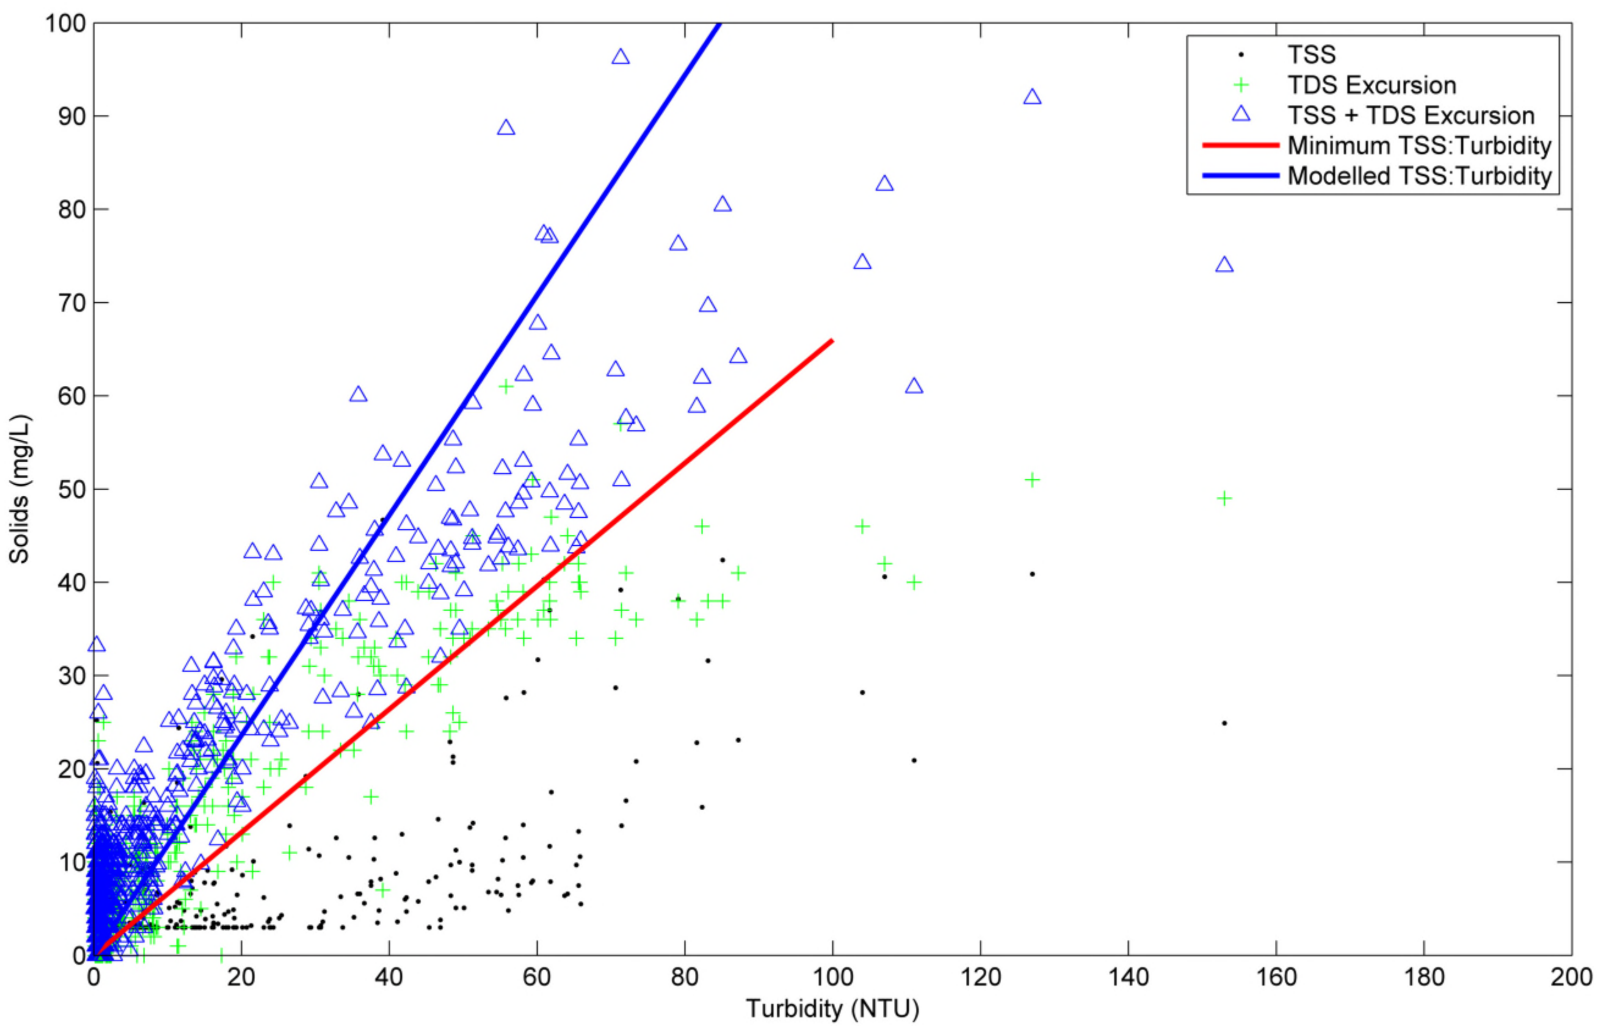
Figure 3.12



NOTES

Data from 1,106 samples collected at various locations in Quesnel Lake, August 2014 - January 2015

TSS (Total Suspended Solids) represents material greater than 1.5 microns in size
TDS includes both dissolved and colloidal material (grain size smaller than 0.45 microns)
The TDS excursion is defined as the measured TDS minus the background TDS of 66 mg/L.
Background is defined solely for the purpose of modelling as the mean of samples from the lake surface

NOTES

Thermistor chains, M2 and M8, operational in 2003-2004.

Significant inflows to Quesnel Lake are Horsefly River, Mitchell River and Niagara Creek. The sole outflow is Quesnel River.

Although it is a minor inflow, Hazeltine Creek is labelled because of its relevance to the TSF breach incident.

APPENDIX A
H3D TECHNICAL DESCRIPTION

APPENDIX A: H3D TECHNICAL DESCRIPTION
ISSUED FOR REVIEW: APRIL 22, 2015

1.0 INTRODUCTION

H3D is an implementation of the numerical model developed by Backhaus (1983; 1985) which has had numerous applications to the European continental shelf, (Duwe et al., 1983; Backhaus and Meir Reimer, 1983), Arctic waters (Kampf and Backhaus, 1999; Backhaus and Kampf, 1999) and deep estuarine waters, (Stronach et al., 1993). Locally, H3D has been used to model the temperature structure of Okanagan Lake (Stronach et al., 2002), the transport of scalar contaminants in Okanagan Lake, (Wang and Stronach, 2005), sediment movement and scour / deposition in the Fraser River, circulation and wave propagation in Seymour and Capilano dams, and salinity movement in the lower Fraser River. H3D forms the basis of the model developed by Saucier and co-workers for the Gulf of St. Lawrence (Saucier et al., 2003), and has been applied to the Gulf of Mexico (Rego et al., 2010).

2.0 THEORETICAL BASIS

H3D is a three-dimensional time-stepping numerical model which computes the three components of velocity (u,v,w) on a regular grid in three dimensions (x,y,z), as well as scalar fields such as temperature and contaminant concentrations. The model uses the Arakawa C-grid (Arakawa and Lamb, 1977) in space, and uses a two level semi-implicit scheme in the time domain. H3D bears many similarities to the well-known Princeton Ocean Model (POM) (Blumberg and Mellor, 1987) in terms of the equations it solves, but differs in how the time-domain aspects are implemented. H3D uses a semi-implicit scheme, allowing relatively large time steps, and does not separately solve the internal and external models as POM does. It also uses a considerably simpler turbulence scheme in the vertical. These considerations combined allow H3D to execute complex problems relatively quickly.

The equations to be solved are:

Mass Conservation:

(A1)

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}+\frac{\partial w}{\partial z}=0$$

At the end of each timestep equation, (A1) is used to diagnostically determine the vertical component of velocity *(w)* once the two horizontal components of velocity (*u* and v) have been calculated by the model.

X-directed momentum:

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}+w\frac{\partial u}{\partial z}+g\frac{\partial \eta}{\partial x}+\frac{1}{\rho_o}\frac{\partial}{\partial x}\int_z^{\eta}(\rho_w-\rho_o)g\,dz-fv-\frac{\partial}{\partial x}A_H\frac{\partial u}{\partial x}-\frac{\partial}{\partial y}A_H\frac{\partial u}{\partial y}-\frac{\partial}{\partial z}A_V\frac{\partial u}{\partial z}=0. \quad \text{(A2)}$$

Y-directed momentum:

$$\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}+w\frac{\partial v}{\partial z}+g\frac{\partial \eta}{\partial y}+\frac{1}{\rho_o}\frac{\partial}{\partial y}\int_z^{\eta}(\rho_w-\rho_o)g\,dz+fu-\frac{\partial}{\partial x}A_H\frac{\partial v}{\partial x}-\frac{\partial}{\partial y}A_H\frac{\partial v}{\partial y}-\frac{\partial}{\partial z}A_V\frac{\partial v}{\partial z}=0. \quad \text{(A3)}$$

Water surface elevation determined from the vertically-integrated continuity equation:

$$\frac{\partial \eta}{\partial t} = -\frac{\partial}{\partial x}\int_{-H}^{\eta} u dz - \frac{\partial}{\partial y}\int_{-H}^{\eta} v dz. \qquad \text{(A4)}$$

The effect of wind forcing introduced by means of the surface wind-stress boundary condition:

$$\left(A_V \frac{\partial u}{\partial z}, A_V \frac{\partial v}{\partial z} \right)_{z=\eta} = \frac{\rho_a}{\rho_w} C_{D,air} \vec{U}_{wind} \left| \vec{U}_{wind} \right|. \qquad \text{(A5)}$$

The effect of bottom friction introduced by the bottom boundary condition:

$$\left(A_V \frac{\partial u}{\partial z}, A_V \frac{\partial v}{\partial z} \right)_{z=-H} = K_{bottom} \vec{U}_{bottom} \left| \vec{U}_{bottom} \right|. \qquad \text{(A6)}$$

The bottom friction coefficient is usually understood to apply to currents at an elevation of one metre above the bottom. The bottom-most vector in H3D will, in general, be at a different elevation, i.e., at the midpoint of the lowest computational cell. H3D uses the ‘law of the wall’ to estimate the flow velocity at one metre above the bottom from the modelled near-bottom velocity.

The evolution of scalars, such as salinity, temperature, or suspended sediment, is given by the scalar transport/diffusion equation:

$$\frac{\partial S}{\partial t} + u\frac{\partial S}{\partial x} + v\frac{\partial S}{\partial y} + w\frac{\partial S}{\partial z} - \frac{\partial}{\partial x} N_H \frac{\partial S}{\partial x} - \frac{\partial}{\partial y} N_H \frac{\partial S}{\partial y} - \frac{\partial}{\partial z} N_V \frac{\partial S}{\partial z} = Q\,. \qquad \text{(A7)}$$

In the above equations:

u(x,y,z,t): component of velocity in the *x* direction;

v(x,y,z,t): component of velocity in the *y* direction;

w(x,y,z,t): component of velocity in the *z* direction;

S(x,y,z,t): scalar concentration;

Q(x,y,z,t): source term for each scalar species

f: Coriolis parameter, determined by the earth’s rotation and the local latitude;

$A_H \left(\partial u / \partial x, \partial u / \partial y, \partial v / \partial x, \partial v / \partial y \right)$: horizontal eddy viscosity;

$A_V \left(\partial u / \partial z, \partial v / \partial z, \partial \rho_{water} / \partial z \right)$: vertical eddy viscosity;

N_H: horizontal eddy diffusivity;

$N_V \left(\partial u / \partial z, \partial v / \partial z, \partial \rho_{water} / \partial z \right)$: vertical eddy diffusivity;

$C_{D,air}$: drag coefficient at the air-water interface;

$C_{D,bottom}$: drag coefficient at the water/sea bottom interface;

ρ_a: density of air;

$\rho_w(x,y,z,t)$: density of water;

ρ_o : reference density of water;

$\eta(x,y,t)$: water surface elevation;

H(x,y) : local depth of water.

The above equations are formally integrated over the small volumes defined by the computational grid, and a set of algebraic equations results, for which an appropriate time-stepping methodology must be found. Backhaus (1983, 1985) presents such a procedure, referred to as a semi-implicit method. The spatially-discretized version of the continuity equation is written as:

$$\eta^{(1)} = \eta^{(0)} - \alpha \frac{\Delta t}{\Delta l}(\delta_x U^{(1)} + \delta_y V^{(1)}) - (1-\alpha)\frac{\Delta t}{\Delta l}(\delta_x U^{(0)} + \delta_y V^{(0)}) \quad \text{(A8)}$$

where superscript *(0)* and *(1)* refer to the present and the advanced time, δ_x and δ_y are spatial differencing operators, and *U* and *V* are vertically integrated velocities. The factor α represents an implicit weighting, which must be greater than 0.5 for numerical stability. $U^{(0)}$ and $V^{(0)}$ are known at the start of each computational cycle. $U^{(1)}$, and similarly $V^{(1)}$, can be expressed as:

$$U^{(1)} = U^{(0)} - g\alpha\Delta t\eta_x^{(1)} - g(1-\alpha)\Delta t\eta_x^{(0)} + \Delta t X^{(0)} \quad \text{(A9)}$$

where $X^{(0)}$ symbolically represents all other terms in the equation of motion for the u- or v-component, which are evaluated at time level *(0)*: Coriolis force, internal pressure gradients, non-linear terms, and top and bottom stresses,*)*. When these expressions are substituted into the continuity equation (A4), after some further manipulations, there results an elliptic equation for $\delta_{i,k}$, the change in water level over one timestep at grid cell *i,k* (respectively the *y* and *x* directions):

$$\delta_{i,k} - (ce\delta_{i,k+1} + cw\delta_{i,k-1} + cn\delta_{i-1,k} + cs\delta_{i+1,k}) = Z_{i,k} \quad \text{(A10)}$$

where *ce*, *cw*, *cn*, and *cs* are coefficients depending on local depths and the weighting factor (α), and $Z_{i,k}$ represents the sum of the divergence formed from velocities at time level *(0)* plus a weighted sum of adjacent water levels at time level *(0).*

Once equation (A10) is solved for $\delta_{i,k}$, the water level can be updated:

$$\eta_{i,k}^{(1)} = \eta_{i,k}^{(0)} + \delta_{i,k} \quad \text{(A11)}$$

and equation (A9) can be completed.

At the end of each timestep, volume conservation is used to diagnostically compute the vertical velocity *w(j,i,k)* from the two horizontal components *u* and *v*.

2.1 Vertical Grid Geometry

In the vertical, the levels near the surface are typically closely spaced to assist with resolving near-surface dynamics. In addition, the model is capable of dealing with relatively large excursions in overall water level as the water level rises and falls in response to varying inflows and outflows, by allowing the number of near-surface layers to change as the water level varies. That is, as water levels rise in a particular cell, successive layers above the original layer are turned on and become part of the computational mesh. Similarly, as water levels fall, layers are turned off. This procedure has proven to be quite robust, and allows for any reasonable vertical resolution in near-surface waters. When modelling thin river plumes in areas of large tidal range, the variable number of layers approach allows for much better control over vertical resolution than does the σ-coordinate method.

In addition to tides, the model is able to capture the important response, in terms of enhanced currents and vertical mixing, to wind-driven events. This is achieved by applying wind stress to each surface grid point on each time step. Vertical mixing in the model then re-distributes this horizontal momentum throughout the water column. Similarly, heat flux through the water surface is re-distributed by turbulence and currents in temperature simulations.

2.2 Turbulence Closure

Turbulence modelling is important in determining the correct distribution of velocity and scalars in the model. The diffusion coefficients for momentum (A_H and A_V) and scalars (N_H and N_V) at each computational cell are dependent on the level of turbulence at that point. H3D uses a shear-dependent turbulence formulation in the horizontal, (Smagorinsky, 1963). The basic form is:

$$A_H = A_{Ho}\, dx\, dy \sqrt{\left(\frac{du}{dx}\right)^2 + \left(\frac{dv}{dy}\right)^2 + \frac{1}{2}\left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}\right)^2} \qquad \text{(A12)}$$

The parameter A_{H0} is a dimensionless tuning variable, and experience has shown it to lie in the range of 0.1 to 1.0 for most water bodies such as rivers, lakes and estuaries.

A shear and stratification dependent formulation, the Level 2 model of Mellor and Yamada (1982), is used for the vertical eddy diffusivity. The basic theory for the vertical viscosity formulation is taken from an early paper, Mellor and Durbin (1975). The evaluation of length scale is based on a methodology presented in Mellor and Yamada (1982).

For scalars, both horizontal and vertical eddy diffusivity are taken to be similar to their eddy viscosity counterparts, but scaled by a fixed ratio from the eddy viscosity values. Different ratios are used for the horizontal and vertical diffusivities. If data is available for calibration, these ratios can be adjusted based on comparisons between modelled and observed data. Otherwise, standard values based on experience with similar previously modelled water bodies are used. For the Quesnel Lake model, the ratio of vertical eddy diffusivity to vertical eddy viscosity was 0.1 for models with only temperature (2003) and 0.5 for models with temperature and suspended material (2014). The ratio between horizontal eddy diffusivity and horizontal eddy viscosity was 1.0.

2.3 Scalar Transport

The scalar transport equation implements a form of the flux-corrected algorithm (Zalesak, 1979), in which all fluxes through the sides of each computational cell are first calculated using a second-order method. Although generally more accurate than a first order method, second order flux calculations can sometimes lead to unwanted high frequency oscillations in the numerical solution. To determine if such a situation is developing, the model examines each cell to see if the computed second order flux would cause a local minimum or maximum to develop. If so, then all fluxes into or out of that cell are replaced by first order fluxes, and the calculation is completed. As noted, the method is not a strict implementation of the Zalesak method, but is much faster and achieves very good performance with respect to propagation of a Gaussian distribution through a computational mesh. It does not propagate box-car distributions as well as the full Zalesak method, but achieves realistic simulations of the advection of scalars in lakes, rivers and estuaries, which is the goal of the model. This scheme as implemented is thus a good tradeoff between precision and execution time, important since in many situations, where more than one scalar is involved, the transport-diffusion algorithm can take up more than half the execution time.

2.4 Heat Flux at the Air-Water Interface

The contribution of heat flux to the evolution of the water temperature field can be schematized as:

$$\frac{dT}{dt} = \frac{\Delta Q}{\rho * c_p * h}$$

where ΔQ is the net heat flux per unit area retained in a particular layer, ρ is the density of water, c_p is the heat capacity of water and *h* is the layer thickness.

Heat flux at the air-water interface incorporates the following terms:

Q_{in}: incident short wave radiation. Generally, this is not known from direct observations. For Quesnel Lake, it was estimated from the cloud cover and opacity observations at Williams Lake Airport, a theoretical calculation of radiation at the top of the atmosphere based on the geometry of the earth/sun system, and an empirical adjustment based on radiation measurements at Vancouver Airport and UBC respectively for the period 1974-1977. This procedure has worked well for other water bodies, notably Okanagan Lake and the waters of the north coast of British Columbia, in terms of allowing H3D to reproduce the observed temperature distributions in space and time. Values for albedo as a function of solar height are taken from Kondratyev (1972).

Q_{back}: net long wave radiation, calculated according to Gill (1982), involving the usual fourth power dependence on temperature, a factor of 0.985 to allow for the non-black body behaviour of the ocean, a factor depending on vapor pressure to allow for losses due to back radiation from moisture in the air, and a factor representing backscatter from clouds.

Q_L and Q_H: latent and sensible heat flux. Latent heat flux (Q_L) is the heat carried away by the process of evaporation of water. Sensible heat flux (Q_S) is driven by the air-water temperature difference and is similar to conduction, but assisted by turbulence in the air. Latent and sensible heat flux is described by:

$$Q_L = 1.32e^{-3} * L * windspeed * (q_{obs} - q_{sat}) * latent\_factor$$

$$Q_S = 1.46e^{-3} * \rho_{air} * c_p * windspeed * (T_{air} - T_{water}) * sensible\_factor$$

Where q_{obs} and q_{sat} are the observed and saturated specific humidities, T_{air} and T_{water} are the air and water temperatures, *L* is the latent heat of evaporation of water, and c_p is the heat capacity of water. '*latent_factor*' and '*sensible_factor*' are scaling factors introduced to account for local factors, and can be adjusted, when needed, to achieve better calibration of the model. Typically, the only adjustment is that *Sensible_factor* is doubled when the air temperature is less than the water or ice surface temperature to account for increased turbulence in an unstable air column.

Light absorption in the water column. As light passes through the water column it is absorbed and the absorbed energy is a component of the energy balance that drives water temperature. H3D assumes that light attenuation follows an exponential decay law:

$$E(z) = E(z_0) * e^{-k*(z-z_0)}$$

The model computes the energy at the top and bottom of each layer and the difference is applied to the general heat equation in that layer. The extinction coefficient (*k*) is related to the Secci depth (D_s) by

$$k = \frac{2.1}{D_s}$$

Temperature is treated like any other scalar as far as advection and diffusion are concerned. Heat flux at the water-sediment interface is not currently included in H3D.

3.0 VALIDATION

Three validations, outside of those presented in the Quesnel Lake report, are discussed below.

3.1 Strait of Georgia/Point Atkinson Tide: Wave Propagation

A fundamental concern with a circulation model such as H3D is how well it propagates waves, the carriers of information through the system. Figure A-1 presents results of a simulation of tides in the Strait of Georgia and Juan de Fuca Strait, with tidal elevations prescribed at the entrance to Juan de Fuca Strait and at a section north of Texada Island in the Strait of Georgia. The complex dynamics of the northern passes, such as Discovery Passage and Seymour Narrows, are thus avoided, allowing a test of H3D's wave propagation capabilities. The figure plots the modelled water level at Point Atkinson in red, and the observed water level in black. There is nearly perfect agreement, with the slight difference resulting from small storm surge events. This validation demonstrates that the selection of grid schematization (Arakawa C-grid) and the semi-implicit time-stepping approach have produced a system than can accurately propagate information through a water body.

3.2 Okanagan Lake Temperature Profiles

Obtaining good reproduction of the seasonally–evolving temperate structure of a lake indicates that the heat flux across the air-water interface is accurately parameterized and that the transport-diffusive processes operating in the water column are also accurately reproduced by the model. Figure A-2 presents a comparison of observed and computed temperature profiles at the northern end of Okanagan Lake near Vernon, in April, August, October and December of 1997. The agreement is very good as the model reproduced the transition from a well-mixed condition in the spring to the development of a strong thermocline in the summer, the deepening of the upper layer during the fall cooling period, and a return to isothermal conditions in winter. There is little doubt that H3D can compute accurate temperature distributions in water bodies, as long as adequate meteorological data is available. For this simulation, the meteorological data was obtained from Penticton Airport: winds, rotated to follow the thalweg of the valley; cloud cover, air temperature and relative humidity.

3.3 Thermistor Response: Okanagan Lake

Okanagan Lake is subject to significant fluctuations in the vertical thermal structure during the summer stratified period. Figure A-3 shows a temperature time-series at a site on the north side of the William R. Bennett Bridge which exhibits significant temperature excursions at periods of about 60 hours, or 2.5 days. Figure A-4 shows the modelled time series of temperature at three selected depths, 51 m, 21 m and 9 m. The occurrence and magnitude of the temperature fluctuations is generally predicted by the model, but the reproduction is not perfect: the occurrence and timing of the temperature events is quite good, but the modelled peaks appear to be generally somewhat broader in time. It was found that there were considerable differences in the simulated behaviour depending on whether winds at Kelowna Airport, which is situated in a side-valley, were included in the model or not. It is also clear that H3D can generally reproduce internal seiches in a lake, as long as adequate spatial resolution is used. This is particularly apparent when the coherent internal waves that propagate up and down the lake are examined in a longitudinal section, illustrated in two snapshots from a model simulation of such an event in Figure A-5.

4.0 COEFFICIENTS USED IN THE QUESNEL LAKE SIMULATION

Model Coefficients

Coefficient	Value	Comment
Vertical levels	-2.25, -1.75, -1.25, -0.5, 0.25, 1, 1.75, 2.5, 3.5, 4.5, 5.5, 6.5, 7.5, 8.5, 9.5, 10.5, 11.5, 12.5, 13.5, 14.5, 15.5, 16.5, 17.5, 18.5, 19.5, 20.5, 21.5, 22.5, 23.5, 24.5, 26, 27.5, 29, 30.5, 32, 33.5, 35, 36.5, 38, 39.5, 41, 42.5, 44, 45.5, 47, 50, 53, 56, 59, 62, 65, 68, 71, 74, 77, 80, 83, 86, 89, 92, 94, 96, 98, 100, 102, 104, 106, 108, 110, 112, 114, 117, 120, 123, 126.66, 131.13, 136.6, 143.2, 151.3, 161.2, 173.3, 188.0, 206.0, 227.9, 254.6, 287.2, 327.0, 375.6, 434.8, 507.1, 600	In depth coordinates, not elevations.
Horizontal grid size	Variable, ranging from 77 x 78 m near Hazeltine Creek to 400 x 700 m at the tip of the East Arm	
Δt	20-22 s, varied according to water velocity	Timestep
A	0.75	Weighting for implicit/explicit solution, more implicit than explicit in this case
Bottom friction coefficient	0.003	
Wind drag coefficient at water surface	1.5×10^{-3}	
A_{Ho}	0.5	Horizontal eddy viscosity coefficient in Smagorinsky formulation
Ah_floor	0.1	Horizontal eddy viscosity minimum (m^2/s)
Kh_factor	1	Ratio between horizontal scalar and velocity mixing
Ratio	0.1 (2003 model), 0.5 (2014 model)	Ratio between vertical scalar and velocity mixing
Av_min	1×10^{-5}	Vertical eddy viscosity minimum (m^2/s)
latent_factor	1.0 if water colder than air, 0.75 if water warmer than air	Latent heat coefficient
sensible_factor	1.0 if water colder than air, 0.75 if water warmer than air	Sensible heat coefficient
Secci	4	Secci disk depth (m)

APPENDIX B
TETRA TECH EBA'S GENERAL CONDITIONS

GENERAL CONDITIONS

DESIGN REPORT

This report incorporates and is subject to these “General Conditions”.

1.0 USE OF REPORT AND OWNERSHIP

This Design Report pertains to a specific site, a specific development, and a specific scope of work. The Design Report may include plans, drawings, profiles and other support documents that collectively constitute the Design Report. The Report and all supporting documents are intended for the sole use of Tetra Tech EBA’s Client. Tetra Tech EBA does not accept any responsibility for the accuracy of any of the data, analyses or other contents of the Design Report when it is used or relied upon by any party other than Tetra Tech EBA’s Client, unless authorized in writing by Tetra Tech EBA. Any unauthorized use of the Design Report is at the sole risk of the user.

All reports, plans, and data generated by Tetra Tech EBA during the performance of the work and other documents prepared by Tetra Tech EBA are considered its professional work product and shall remain the copyright property of Tetra Tech EBA.

2.0 ALTERNATIVE REPORT FORMAT

Where Tetra Tech EBA submits both electronic file and hard copy versions of reports, drawings and other project-related documents and deliverables (collectively termed Tetra Tech EBA’s instruments of professional service), only the signed and/or sealed versions shall be considered final and legally binding. The original signed and/or sealed version archived by Tetra Tech EBA shall be deemed to be the original for the Project.

Both electronic file and hard copy versions of Tetra Tech EBA’s instruments of professional service shall not, under any circumstances, no matter who owns or uses them, be altered by any party except Tetra Tech EBA. Tetra Tech EBA’s instruments of professional service will be used only and exactly as submitted by Tetra Tech EBA.

Electronic files submitted by Tetra Tech EBA have been prepared and submitted using specific software and hardware systems. Tetra Tech EBA makes no representation about the compatibility of these files with the Client’s current or future software and hardware systems.

3.0 ENVIRONMENTAL AND REGULATORY ISSUES

Unless so stipulated in the Design Report, Tetra Tech EBA was not retained to investigate, address or consider, and has not investigated, addressed or considered any environmental or regulatory issues associated with the project specific design.

4.0 CALCULATIONS AND DESIGNS

Tetra Tech EBA has undertaken design calculations and has prepared project specific designs in accordance with terms of reference that were previously set out in consultation with, and agreement of, Tetra Tech EBA’s client. These designs have been prepared to a standard that is consistent with industry practice. Notwithstanding, if any error or omission is detected by Tetra Tech EBA’s Client or any party that is authorized to use the Design Report, the error or omission should be immediately drawn to the attention of Tetra Tech EBA.

5.0 GEOTECHNICAL CONDITIONS

A Geotechnical Report is commonly the basis upon which the specific project design has been completed. It is incumbent upon Tetra Tech EBA’s Client, and any other authorized party, to be knowledgeable of the level of risk that has been incorporated into the project design, in consideration of the level of the geotechnical information that was reasonably acquired to facilitate completion of the design.

If a Geotechnical Report was prepared for the project by Tetra Tech EBA, it will be included in the Design Report. The Geotechnical Report contains General Conditions that should be read in conjunction with these General Conditions for the Design Report.

6.0 INFORMATION PROVIDED TO TETRA TECH EBA BY OTHERS

During the performance of the work and the preparation of the report, Tetra Tech EBA may rely on information provided by persons other than the Client. While Tetra Tech EBA endeavours to verify the accuracy of such information when instructed to do so by the Client, Tetra Tech EBA accepts no responsibility for the accuracy or the reliability of such information which may affect the report.

Executive Summary

A tailings dam failure occurred at the Mount Polley Mine (MPM), located approximately 55 km north-east of Williams Lake, BC, on August 4, 2014. The dam failure resulted in spillage of tailings and other materials into Polley Lake, Hazeltine Creek, and Quesnel Lake. SRK developed and carried out a geochemical characterization program to assess the metal leaching and acid rock drainage (ML/ARD) potential of the spilled tailings that included a review of existing data, a geochemical conceptual model to guide sampling design, and a sampling and analysis plan. Results of the program are provided herein, although at the time of this report certain tests were on-going and the interpretations provided in this report are therefore considered interim.

The geochemical conceptual model developed indicated that ML/ARD potential needed to be assessed for two main storage conditions: (1) subaerial tailings along the banks of Hazeltine Creek and (2) subaqueous tailings along the stream bed of Hazeltine Creek and in Polley and Quesnel Lakes. The spilled tailings likely mixed to varying degrees with native sediments during and after the dam failure and during deposition. Therefore, geochemical characterization and reference to ‘spilled tailings’ herein is inclusive of any co-mingled native sediments.

Sampling was conducted along Hazeltine Creek by SRK and SNC-Lavalin. Minnow Environmental Inc. also sampled tailings from along the creek and from the bottom of Quesnel and Polley Lake. Characterization tests were designed to provide information on acid-base accounting, tailings composition, mineralogy, and leaching potential characteristics of the tailings under subaerial (i.e. humidity cell and column tests) and sub-aqueous (i.e. sequential extractions) storage configurations.

Sampling results were such that acid rock drainage potential of the spilled tailings is considered to be negligible owing to low sulphur content (ranging from 0.1 to 0.3%) and high buffering potential from calcite. As a result, leaching from the spilled tailings needs to be considered only as under non-acidic conditions (i.e. typical conditions in natural streams and lakes) rather than acidic conditions.

Element screening tests, which were based on an industry standard technique of comparing solid phase concentrations in the spilled tailings to average concentrations in similar rock types, found that the only enriched elements in the spilled tailings were copper and selenium. Screening the elements on the basis of enrichment is a common approach to identifying elements for further consideration in a geochemistry program. However, screening on its own does not preclude elimination of considerations for element leaching under particular environmental conditions. On-going geochemical testing and site specific application will be needed to further evaluate element leaching.

The association of these enriched elements (copper and selenium) is with sulphides, which is a typical mineralogical relationship. A portion of copper (approximately 20%) was also found to be associated with relatively insoluble, slow weathering silicates. Copper solubility at neutral pH is also low due to oxide formation as compared to much higher solubility under acidic conditions and, as a result, leaching of copper from the tailings is expected to be low. Selenium is more

soluble than copper at neutral pH and does not appear to be associated with silicates. However, given the relatively thin deposition of tailings along the creek and high dilution potential from precipitation and other sources, selenium concentrations are likely to be low. Kinetic testing is underway to confirm this expectation and MPMC's ongoing environmental monitoring program will detect if selenium concentrations begin to change.

Tailings that settled in Quesnel and Polley Lakes are expected to be geochemically stable and not readily soluble. Only a small proportion of mineral forms that could be susceptible to reductive dissolution were found in the samples, and neither copper nor selenium were significantly associated with these forms. Water saturation will effectively inhibit oxidation of the sulphides in the tailings; therefore, leaching of elements like copper and selenium that require oxidation to be released will effectively be inhibited.

1 Introduction

A tailings dam failure occurred at the Mount Polley Mine (MPM), located approximately 55 km north-east of Williams Lake, BC, on August 4, 2014. The dam failure resulted in the release of tailings and water contained within the tailings dam into Polley Lake, Hazeltine Creek, and Quesnel Lake. Production at the MPM ceased after the dam failure and the mill was placed on care and maintenance.

SRK was retained to develop and execute a plan and to characterize the geochemical characteristics of the tailings materials released from the Tailings Storage Facility (TSF). The plan included a review of existing data, a geochemical conceptual model to guide sampling design, and a sampling and analysis plan.

Geochemical characterization results are presented and discussed herein, although certain tests, described below, are on-going and the results are considered interim. Conclusions based on currently available data of the metal leaching and acid rock drainage (MLARD) potential of exposed tailings along Hazeltine Creek and the tailings deposited in Quesnel and Polley Lakes are provided.

2 Background

2.1 Geological Setting

The Mount Polley deposit is classified as an alkalic porphyry copper gold deposit (BC MINFILE No. 093A 008). It has been mined from several different mineralized zones, which have the following common features:

- The host rocks for porphyry mineralization are intrusions into the Nicola Volcanics varying in composition from diorite to syenite.
- Alteration is potassic (secondary biotite and pink orthoclase) and propylitic (calcite-epidote-chlorite-pyrite).
- Sulphide mineralization consists mainly of chalcopyrite ($CuFeS_2$) and pyrite (FeS_2), with lesser bornite (Cu_5FeS_4), covellite (CuS), and digenite (Cu_9S_5).
- Carbonate mineralization is principally calcite, with occurrences of malachite ($Cu_2CO_3(OH)_2$); Iron carbonates have not been reported.
- A significant portion of the copper at the MPM is not associated with sulphides (upwards of 50% in the upper portions of each pit). This fraction has been termed ‘copper oxide’ by MPM personnel and is associated primarily with chrysocolla ($(Cu,Al)_2H_2Si_2O_5(OH)_4 \cdot nH_2O$) and malachite ($Cu_2CO_3(OH)_2$) in equal proportions (Henry 2009). The term ‘copper oxide’ is not used hereafter in this report; however, other reports produced by MPMC do use this term to describe non-sulphide associated copper.

2.2 Ore Processing History

Understanding the ore processing history at the MPM is important because it may help identify processing changes over time that could have altered the geochemical reactivity of the tailings. Potential differences in reactivity can then be assessed in terms of potential quantity and also possible storage conditions after the dam failure (i.e. subaerial versus subaqueous).

Flow-sheets for the entirety of operations at the MPM were provided to SRK, along with records of ore and tailings production, and percentage of non-sulphide associated copper in the ore and tailings. Composition of the tailings produced in the mill prior to the dam failure is provided in Section 5.6.4. Processing history information was provided to SRK by the MPMC. SRK Principal Metallurgist, Adrian Dance, reviewed the flow sheets to identify processing changes that may have altered the composition of the tailings. A summary of the ore processing history and grinding and flotation circuit changes over the years of operation is provided in Table 2-1. The flow sheet for the flotation circuit in 2014 is provided in Appendix A as an example for processing steps at the mine.

The main product produced from mining the Mount Polley ore body is a copper sulphide concentrate. In general terms, the concentrate is produced by blasting the ore, primary and secondary crushing, grinding, rougher flotation and cleaner flotation. The majority of the plant feed is disposed of as tailings following the flotation separation stage. As the goal of flotation is to concentrate sulphides, the tailings are lower in sulphide minerals compared to the original ore feed.

Mill process reagents that were added to the mill are typical of sites that float copper sulphides and included methyl isobutyl carbinol (MIBC), xanthates and lime (calcium oxide). Sodium hydrogen sulphide (NaHS) was added to the crushed ore slurry to bind to the surface of the non-sulphide copper containing minerals and enable them to be recovered in the same manner as the copper sulphide minerals. While sulphides are the predominant economic mineral in the ore, the near surface portions of the ore body have naturally oxidized prior to mining, and as a result, a varying amount of non-sulphide copper needed to be processed. The non-sulphide component generally decreased as mining progressed in each pit. With the exception of lime, the process reagents are not expected to be present with the spilled tailings as they would either have remained with the concentrate (chemically bound to mineral surfaces) or degraded quickly in the environment. This was confirmed by testing of tailings along Hazeltine Creek by MPMC and the BC Ministry of the Environment as results for MIBC and xanthates (and their degradation products) showed that concentrations were below detection in all samples tested (MPMC 2014a).

The main processing phases over the life of mine are provided in Table 2-1. The mine was shut down from the end of 2001 until the beginning of 2005 due to low metal prices. The three most significant processing changes were (1) incorporation of an oxide recovery unit, (2) addition of ‘flash’ flotation, and (3) addition of a magnetite separation unit. These changes are relatively minor in terms of altering the geochemical reactivity of the tailings; consequently, the tailings geochemistry can be considered in aggregate.

Changing relative abundance of non-sulphide copper ore appears to be the most significant variable for geochemical reactivity of the tailings. Non-sulphide copper has accounted for as much as 67% of the total copper in the tailings (Figure 2-1); although, copper is a relatively minor component of the tailings (i.e. 67% non-sulphide copper of 0.3% total copper). The two downward trends observed in Figure 2-1 represent mining progressing to depth in the Springer and Cariboo open pits (the most weathered ore is near the surface of each pit).

Table 2-1: Ore processing summary for the Mount Polley Mine.

Year of Production	Ore Processed (tonnes)	Tailings Produced (tonnes)	Grinding Circuit	Sources of Tailings	Changes and Geochemical Considerations
Mine Start in 1997	2,346,829	2,333,186	2 rod, 2 ball, 3 pebble mills	Three tailings streams: (1) sand scavenger; (2) oxide; and (3) cleaner tails from cyclone overflow. All streams combined for disposal in the impoundment.	NaHS used to float non-sulphide copper minerals.
1998	5,828,358	5,788,498			
1999	7,051,212	6,986,932			
2000	6,948,339	6,883,317			
2001	5,385,796	5,328,581			
5 year shutdown					Consolidation of the tailings in the impoundment
2005	4,814,083	4,758,757	2 rod, 2 ball, 3 pebble mills	Two streams; rougher and scavenger tails. Both streams combined for disposal in the impoundment	Higher proportion of sulphide ore and lower NaHS addition
2006	6,235,221	6,133,088			
2007	6,444,112	6,346,640	2 rod, 3 ball, 3 pebble mills		Addition of third ball mill to increase production from 6.4 to 7 million tonnes per annum (Mtpa)
2008	6,848,983	6,735,444			
2009	7,045,737	6,977,681			
2010	7,894,596	7,825,178	2 rod, 3 ball, 3 pebble mills and flash flotation		Addition of flash flotation for remainder of operations to date with the potential to lower sulphide content in the tailings
2011	7,716,856	7,663,577		One stream combined	More weathered ore and higher NaHS addition
2012	8,121,878	8,056,496		One flotation stream and addition of circuit to remove magnetite	Addition of magnetite removal circuit. Tailings produced after 2012 would contain lower amounts of magnetite.
2013	7,956,738	7,882,625			
2014	4,548,182	4,502,145

2.3 Tailings Deposition History

Understanding tailings deposition history at the MPM is important because it may help identify deposition changes over time that could have resulted in varying geochemical characteristics of tailings that spilled from the TSF.

The following summary of the tailings deposition history at the MPM is based on input from the MPMC.

Tailings slurry produced in the mill is gravity-fed to the TSF with deposition by single-point discharge and using “sand cell” construction. The sand cell method was used to the maximum extent possible to encourage drainage of the tailings and to keep the piezometric surface as far from the embankment as possible. During operations, the discharge point was sequentially rotated along the entire length of the three embankments (i.e. the Perimeter, Main, and South Embankments) on the upstream face, allowing inactive areas of the tailings beach to partially dry and consolidate. The goal of rotating deposition was so that beaches would form around the entire upstream perimeter of the TSF and supernatant water containing fines would centralize around the TSF supernatant reclaim barge.

Sand cells were built in 100 m lengths, 25 to 30 m wide and varied in height with the beach management requirements (height versus advancement around dam). They were constructed by creating a “cell” out of existing tailings and waste rock with a decant structure at the end of the cell. Tailings were introduced into the cell by single-point discharge from the tailings line, and allowed to flow through the cell, the coarser layer being contained in the cell. A modified bulldozer was used to “work” the material in order to optimize material retention. The fine or “slimes” fraction reported to the tailings pond by means of the decant structure and formed beaches.

Based on the tailings deposition history provided by MPMC, the tailings produced during operations would have been well mixed and there appears to have been limited potential to create anomalous zones in the impoundment.

3 Initial Geochemical Conceptual Model

3.1 Basis

An initial geochemical conceptual model (IGCM) was formulated in September 2014 to guide the design of the characterization approach for the spilled tailings. It was based on current understanding of the site geology, ore processing, tailings deposition, and SRK’s experience at other sites prior to gathering the data presented subsequently in the report. The IGCM effectively represents hypotheses about tailings characteristics and reactivity which are subsequently evaluated through observations, sampling, testwork and interpretation.

The two main configurations of the spilled tailings are:

- Subaerial tailings along the banks of Hazeltine Creek.
- Subaqueous tailings along the stream bed of Hazeltine Creek, and in Polley Lake and Quesnel Lake.

The above two storage configurations are discussed in Section 3.2 and 3.3.

3.2 Subaerial Tailings

The tailings that spilled from the TSF and were deposited along the banks of Hazeltine Creek above the water table will be exposed to atmospheric conditions. MPM tailings contain sulphide and carbonate minerals, which will react in the presence of atmospheric oxygen to yield water soluble components. The rate at which these reactions occur and significance for impacts to water quality depends on the chemical and physical characteristics of the tailings, as well as their final deposition configuration. Physical characteristics are important as fine grained material is less likely to allow gas diffusion and weathering of the tailings can be depth limited, as compared to coarser sand like tailings where gas diffusion is not as limited and weathering can proceed relatively unimpeded.

Based on the review of ore processing, tailings composition and tailings deposition history provided by the MPMC, the composition and physical characteristics of the spilled tailings is expected to be fairly homogeneous. However, some degree of tailings mixing with natural sediments likely occurred, so the materials along the banks of Hazeltine Creek may be a heterogeneous mixture of tailings and natural sediments. The pre-existing sediments likely have low sulphide content and as a result, the tailings will dominate reactivity of the mixture. As a result, any reference to the term ‘spilled tailings’ herein is inclusive of co-mingled native sediments.

On the basis of the composition of the tailings in the TSF, ARD is not expected and element leaching needs to be considered only under neutral drainage conditions. While elements like copper would be expected to be enriched in the tailings, leaching of this element would likely be low due to metal oxide formation at neutral pH.

The goal of sampling is to confirm that the compositional variability of tailings and any co-mingled natural sediments is low, and to confirm that mineral weathering only needs to be considered under neutral pH conditions. This is important to note as mineral and element specific solubility is often much lower under neutral pH conditions than acidic pH conditions.

3.3 Subaqueous Tailings

The majority of tailings that were contained within the TSF prior to the dam failure were stored underwater. Sulphide oxidation, and any element leaching from sulphide oxidation, would have effectively been inhibited due to the solubility of oxygen in water being orders of magnitude lower than the atmosphere (i.e. 21% atmospheric versus 0.001% in water at 10°C). Secondary mineral formation from weathering (e.g. iron oxyhydroxides) would also have been limited, although the unsaturated portions of the beaches may have formed secondary minerals that could have sequestered certain elements. The potential water quality impacts from re-deposition of tailings in a new subaqueous environment is expected to be mainly dependent on pH and oxidation reduction potential (redox). The aerobic portions of Hazeltine Creek, Polley Lake and Quesnel Lake would likely be geochemically similar to the TSF conditions, as these waters are not acidic and therefore leaching potential is expected to be limited. The main consideration for water quality impacts is from any secondary minerals formed (e.g. iron oxyhydroxides) that are deposited in an anaerobic environment and susceptible to reductive dissolution. Secondary minerals may have formed in the unsaturated portions of the tailings before the dam failure, or during in-situ weathering of the ore deposit before mining.

Additional sampling would not be required to address this question, but geochemical characterization would need to consider leachable mineral forms under varying subaqueous redox conditions. Geochemical characterization tests were designed to consider leachable mineral forms as outlined in Section 4.3.

4 Geochemical Characterization Methods

4.1 Overview

The geochemical characterization data provided in this report were obtained through implementation of SRK's Characterization Plan (SRK 2014). The plan was developed to address assumptions made in the conceptual model, with the overall goal of assessing how the reactivity of the spilled tailings may impact water quality.

In brief, the plan consisted of field sampling along Hazeltine Creek and a series of geochemical tests to understand the composition, mineralogy and leaching characteristics under various storage configurations. SRK focused on the spilled tailings along Hazeltine Creek because weathering under sub-aerial conditions should represent the most likely scenario for leaching based on the IGCM. In addition, Minnow Environmental's scope included sampling of spilled tailings that settled in Polley and Quesnel Lakes. Between the historical data, and two independent sampling campaigns, the assumption was that geochemical variability would be characterized.

The following sections provide specific details of how the plan was implemented. The plan also included considerations for sampling tailings remaining within the impoundment, but due to safety considerations at the time of the field program and results for tailings available from historical mill sampling, sampling of material within the TSF was precluded.

4.2 Field Sampling

Representatives of SRK and SNC Lavalin collected samples from the banks of Hazeltine Creek between September 8, 2014 and September 19, 2014 as described in a letter dated November 10, 2014 and posted on MPMC's website (MPMC 2014b). For ease of reference, the main components of the field sampling program are summarized in Section 4.2.1.

4.2.1 Hazeltine Creek Sample Collection

Samples of exposed spilled tailings in Hazeltine Creek were collected along 18 parallel transects, oriented roughly perpendicular to the course of Hazeltine Creek, spaced approximately 500 m apart beginning with transect ST17/18 in the area of the dam dam failure and ending with transect ST01 near the mouth of Hazeltine Creek at Quesnel Lake (Figure 4-1). At each transect, major physical/depositional features were sampled, with up to five samples per transect. Physical/depositional features were determined in the field based on particle size (fine grained versus coarse), colour, or depositional area (e.g. high on a bank or shoulder versus adjacent to the creek). In total, 108 samples were collected, of which 68 were identified as spilled tailings samples. The remainder of samples consisted of native sediments beneath tailings and soils outside of the impacted area.

A site-specific methodology for sampling along Hazeltine Creek was developed by SRK and SNC representatives based on professional experience using best practice to ensure sampling was un-biased and properly characterized geochemical variability. Since the spilled tailings had not been sampled previously, the program allowed for the possibility that additional sampling would be needed to understand variability of critical geochemical characteristics of the spilled tailings but in practice the program provided sufficient data with a second field program. Details of the sampling method are provided below.

Sample locations at each transect were determined by multiplying the length of the field identified feature by a random decimal number (from a list of random decimals generated in Excel). The result of this random number multiplication was the distance (along the transect) within the feature where the sample was to be taken. For each transect, zero distance was the location of the background sample, which alternated between the east and west side of Hazeltine Creek. As an example, a feature 10 m long and a random number of 0.2, the sample would be taken 2 m from the start of the transect. Additionally, special interest samples could be taken for discrete material types that did not comprise an entire depositional feature.

Samples were collected from test-pits that were hand-dug using a clean shovel. Material was collected at depth within the test-pits using a clean trowel. Plant roots and other organics were excluded as much as possible. Detailed logs of each sample test-pit are provided in SNC (2015).

Duplicates and replicates of approximately 10% of the samples were collected for quality assurance and quality control (QA/QC) and assessment of sample variability. For duplicate sample collection, material was split evenly among two sampling containers each time it was brought up from depth. Replicate sample collection to assess variability was performed by multiplying a random number by 360 degrees to determine a bearing from the location of the initial sample. The replicate sample was collected 1 m away from the initial sample along the determined bearing.

Three silica sand blanks were also submitted as ‘blind’ samples to the laboratory as part of QA/QC procedures. They were placed into the same sample bags using field equipment to evaluate potential contamination sources during sampling, in transport, and in the laboratory.

4.2.2 Sequential Extraction Sample Collection

A total of 78 additional samples were collected from the study area for sequential extraction analyses by Minnow Environmental between August 13 and October 24, 2014. Specific details of the sample collection procedures and locations are provided in Minnow (2015). Of the samples collected, 18 were from the profundal zone in Quesnel Lake (6 lake sediment samples and 12 spilled tailings), 18 were from the littoral zone in Quesnel Lake (2 lake sediment samples and 16 spilled tailings), and 15 were spilled tailings from along Hazeltine Creek. Fifteen samples from the bottom of Polley Lake were also collected by Minnow Environmental. The Hazeltine Creek samples were collected along the same transects as described in Section 4.2.1, but collected by Minnow Environmental on different dates and distances along each transect.

4.3 Laboratory Analyses for Hazeltine Creek Samples

A two-phase testing approach was used for geochemical characterization in order to constrain composition variability and understand specific acid-base accounting (ABA) and mineralogical characteristics of the Hazeltine Creek samples as previously outlined in SRK's Characterization Plan (SRK 2014).

4.3.1 Phase 1

Phase one testing included the following analyses on samples from Hazeltine Creek:

- Moisture content.
- Multi-element analysis, including sulphur content by aqua regia digestion with an inductively coupled plasma mass spectrometry (ICP-MS) finish (ALS code ME-MS41).
- Total inorganic carbon (TIC).

Particle size distribution by sieving was also performed on approximately 25 % of the samples. The analyses were conducted by ALS Environmental in Burnaby, British Columbia.

4.3.2 Phase 2

Approximately 25% (19) of the Hazeltine Creek samples were submitted for a second phase of testing to confirm ABA assumptions and define mineralogical characteristics of the samples and rates of weathering. Samples were selected to capture the range of sulphur, TIC, copper, and selenium content in the Hazeltine Creek samples based on the results of the phase 1 analyses (Table 4-1). Copper and selenium were part of the considerations for sample selection due to their enrichment in the samples. The rationale for 'tailings type' (i.e. magnetite sand and grey tailings) is provided in Section 5.1.

Prior to any analytical testing, some samples were composited as outlined in Table 4-2. For samples that were composited, new sample identifications were provided. Prior to compositing, 200 grams (g) of material from each sample was retained for archiving purposes. Composited samples were well mixed by the analytical laboratory and splits of the homogenised composites were taken for the various Phase 2 tests.

Table 4-1: Hazeltine Creek Tailings Samples Selected for Phase 2 Analyses

Sample ID	Tailings Type	S (%)	TIC (kg $CaCO_3$/t)	Cu (mg/kg)	Se (mg/kg)

The 15 samples listed in Table 4-2 were submitted for the following additional tests at ALS:

- Paste pH and conductivity.
- Modified Sobek Neutralization Potential determination (MEND 1991).

- Total sulphur (by LECO furnace) and sulphate sulphur (by hydrochloric acid (HCl) leach).
- Non-sulphide copper analysis using a method developed by the MPM, as follows
  - Dried samples were leached using 2.5% sulphuric acid (H_2SO_4). The acidic slurry was mixed using a vortex shaker and then placed on a shaker table for 90 minutes. The sample was allowed to settle and leachate was filtered and submitted for ICP-MS multi-element scans (35 elements including sulphur and low level selenium).
- Two samples were randomly selected by ALS to serve as duplicates for QA/QC purposes.

4.3.3 Kinetic Testing Program

The kinetic testing program consists of six standard laboratory humidity cells (HCs), three column leach tests, two blanks (a HC and a column), and one HC duplicate (Table 4-3). The intent of the program is to establish weathering rates under oxygen unlimited conditions using humidity cell testing and then use column tests to evaluate the effect of reduced leaching rates. As a result, composites were prepared to represent the range of geochemical variability identified during phase one testing, but to also be of sufficient volume that splits of each sample could be taken for testing in humidity cells and columns.

Table 4-3: Composite preparation requirements and sample labelling.

Kinetic Test ID	Tailings Type	Original Sample IDs
HC-1/COL-1	Magnetite Sand	Composite of ST11-02-02, ST12-02 and ST11-02-1
HC-2/COL2	Magnetite Sand	Composite of ST16-02 and ST01-03
HC-3/COL-3; HC-3D	Grey Tailings	Composite of ST08-02-01 and ST13-03
HC-4	Grey Tailings	ST01-05-02
HC-5	Magnetite Sand	ST02-05-02
HC-6	Grey Tailings	ST17-08-01
HC-7	Blank	
COL-4		

P:\01_SITES\Mt_Polley\1CI008.003_Privileged_and_Confidential\500_Reporting\Interpretations\Geochemistry\Hzltn_Crk_2014\[PhII_sample_selections_1CI008.003_REV00_CBK.xlsx]

The HCs were set up according to the methods described in the 1991 Mine Environment Neutral Drainage Program's Acid Rock Drainage Prediction Manual (MEND 1991). The two major sample mixture/tailings types identified in the field, (1) magnetite sands tailings and (2) grey tailings, were both tested. The duplicate cell (HC-3D) is a split from HC-3. The blank cell (HC-7) was constructed using the exact same material and adhesives as the other cells and is running according to the same procedures.

The column tests, including the blank, were constructed from plexiglass (acrylic) with a 10 cm inner diameter and a perforated base supporting two layers of nylon screen (400 mesh). The columns were filled with 500 g of tailings and are being trickle leached with 500 mL of water per week.

Weekly leachate analyses were performed for the first month of the kinetic testing program. The analysis frequency will then change to bi-weekly analyses for all parameters except pH, conductivity, and volume of leachate recovered, which will continue to be recorded weekly.

At the time of this report, three cycles of data had been received from the humidity cells and only one cycle had been recovered from the columns. Typically these tests run for a minimum of 40 weeks and meaningful results are usually not available until after 20 weeks.

4.3.4 Mineralogy

Mineralogical characterization using Quantitative Evaluation of Minerals by Scanning Electron Microscopy (QEMSCAN) was conducted on 100 g splits from all of the kinetic test program samples (Table 4-1), including the duplicate. Analysis was performed by SGS Canada Inc. in Burnaby, BC.

QEMSCAN is a relatively new mineralogical method being used for environmental geochemistry applications and it provides modal mineralogy based on mineral grain chemistry. The method is advantageous over optical petrography methods as many more mineral grains can be analyzed and quantitative information on particle size and degree of mineral liberation/exposure can also be obtained.

As part of the QEMSCAN characterization of the samples, Rietveld X-ray diffraction (XRD) and electron microprobe were selectively used to refine and confirm modal abundances, mineral form (e.g. the different iron oxides present) and element deportment for low concentrations that could not be resolved by QEMSCAN.

4.3.5 Sequential Extractions

Sequential extractions involve a progressive series of chemical extractions applied to the same sample in order to divide the total metal content into geochemical ‘fractions’. Each fraction is the result of dissolution of certain types of minerals using specific reagents. The sequential extractions conducted for the MPM tailings were performed by ALS Minerals in Burnaby, BC as designed and directed by Minnow Environmental (Minnow 2015) and based on the Tessier procedure (Tessier et al. 1979).

The design targeted elements that were exchangeable and adsorbed, associated with carbonates, reducible minerals (i.e. iron oxides), organically-bound metals and residual metals. Water soluble constituents were also determined on splits of the same sample using the shake flask extraction (SFE) method (MEND 2009).

The reagents used for the sequential extractions and noted modifications to the procedure are provided in Table 4-4. The procedure as intended by Tessier and the modifications applied by Minnow were designed for soils, and as a result, some of the reagents used would likely target different mineral fractions in tailings than they would in soils. The three main deviations identified include:

- Easily reducible iron oxides - the reagents used likely result in dissolution of other mineral groups in addition to the easily reducible iron oxides.
- Organically bound metals – as there are expected to be limited amounts of organic materials in the tailings due to the nature of the ore, the reagents and temperatures used likely oxidize some of the sulphide and may also leach more resistant oxide minerals. Tessier et al. (1979)

also noted some alteration of the minerals smectite, chlorite and mica in this digestion step. These minerals are present in the MPM tailings.

- Residual metals – a four acid digestion was not performed and instead replaced by aqua regia which will not completely dissolve silicates and is likely most representative of metals associated with sulphides. In addition, aqua regia digestion was performed on the minus 2 mm fraction, not pulverized samples, which can result in incomplete digestion.

In order to avoid confusion in comparison of results from different programs, the naming of each fraction from the sequential leaching has not changed, but results will be discussed in the context of the above differences.

Table 4-4: Description of Sequential Extraction Method (modified after Tessier et al. 1979)

Step	Mineral Fraction	Reagent	Procedure	Deviation from Tessier et al. 1979
I	Exchangeable & Adsorbed	magnesium chloride (1 M $MgCl_2 \cdot 6H_2O$)	1. Add 16 mL of reagent	ALS doubled the method to ensure that there was enough sample for analysis.
			2. Place on shaker table (1 hour)	
			3. Centrifuge on high (30 minutes)	
			4. Pipette the supernatant into a centrifuge tube for analysis	
			5. Add 16 mL of deionized water to the tube with the sediment, hand shake (1 minute)	
			6. Pipette supernatant	
			7. Discard supernatant	
II	Carbonate Metal	sodium acetate (1 M NaOAc)	1. Add 16 mL of reagent, adjust pH to 5 using acetic acid (HOAc) if necessary	Tessier states to shake for 5 hours. 2.5 hours applied.
			2. Place on shaker table (2.5 hours)	
			3. Repeat steps 4-7 as in Step I	
III	Easily Reducible and Iron Oxides	hydroxylamine hydrochloride in acetic acid (0.1 M NH_2OH-HCl (25% V/V in HOAc))	1. Add 40 mL of reagent	--
			2. Hand shake (1 minute)	
			3. Place in oven at 96 ± 3 ºC (6 hours), hand shake every hour and after 6 hours	
			4. Repeat steps 4-7 as in Step I	
IV	Organic Bound Metal	nitric acid followed by ammonium acetate (0.02 M HNO_3 then 3.2 M NH_4OAc)	1. Add 6 ml of 0.02 M HNO_3	--
			2. Add 10 mL of 30% H_2O_2 and adjust to pH 2 with HNO_3	
			3. Hand shake (1 minute)	
			4. Place in the oven at 85 ± 2 ºC (2 hours), shake at the end of 1 and 2 hours	
			5. Add 6 mL of H_2O_2 (adjust to pH 2 with HNO_3 if necessary) and hand shake	
			6. Heat to 85 ± 2 ºC (3 hour), shake every hour	
			7. Cool sample	
			8. Add 10 mL of 3.2 M NH_4OAc in 20% V/V HNO_3	
			9. Add 8 mL H_2O (dilute to 40mL)	
			10. Shake with a wrist shaker (30 minutes)	
			11. Repeat step 4-7 as in Step I	
V	Residual Metal	Aqua regia (CSR (EPA 200.2))	1. Add 10 mL of deionized water, 5 mL of HNO_3 and 5 mL of HCl	Tessier states digestion using $HF/HClO_4$.
			2. Cold digest (60 minutes)	
			3. Digest for 2 hours ± 15 minutes at sub-boiling reflux temperature	
			4. Cool	
			5. Bulk to 50 mL with deionized water, cap and shake.	

P:\01_SITES\Mt_Polley\1CI008.003_Privileged_and_Confidential\500_Reporting\Interpretations\Geochemistry\Seq_extractions\[Tessier_Interp_1CI008003_REV00_SJD_CBK.xlsx]

5 Results

5.1 Hazeltine Creek Field Observations

Photographs from field sampling are provided in Appendix B. A sample list and descriptions of the Hazeltine Creek samples used in this geochemical characterization study are provided in Appendix C1.

Two types of tailings-bearing samples were observed along Hazeltine Creek. They were classified in the field as ‘grey tailings’ and ‘magnetite sands’. This classification was based on physical and mineralogical characteristics as follows:

- Grey tailings were dominantly grey in colour and had a finer texture (silty sand) than the magnetite sands. They had a strong reaction (referred to as “fizz”) with 10% HCl and did not contain sulphide minerals that were visible by examination with a hand lens. Mineral identification was difficult due to small grain size, but the dominant minerals included potassium feldspar and plagioclase, with minor biotite mica and quartz.
- Magnetite sands were speckled pinkish-orange and black. They were strongly magnetic and coarser (sand) than the grey tailings. They had weak fizz and trace (less than 1%) sulphide minerals were infrequently noted. The dominant minerals identified included plagioclase feldspar and magnetite. Biotite mica and quartz appeared more abundant than in the grey tailings.

The grey tailings tended to be most abundant along the embankments and upper benches of the creek, whereas the magnetite sands were commonly present in low-lying areas near the creek. With the exception of the area near the tailings dam failure and Polley Lake, the tailings were deposited in relatively thin ‘skiffs’ (e.g. 10 to 20 cm deep). The thickest observed tailings deposits (e.g. 1 to 1.5 m deep) were in the immediate vicinity of the tailings dam failure and Polley Lake (SNC-Lavalin 2015).

5.2 Quality Assurance and Quality Control

5.2.1 Overview

In addition to the normal laboratory QA/QC procedures, field duplicates and field blanks were assessed for QA/QC. Results of the assessment are provided in Appendix C2. Based on the QA/QC measures taken for this program, SRK’s overall conclusion is that the data quality is acceptable. A summary of the procedures for duplicates and blanks is provided below.

5.2.2 Duplicates

The duplicates were assessed with respect to a relative percent difference (RPD) target of 25%. RPD was calculated using the equation below, where ‘x’ is the concentration of the original sample and ‘y’ is the concentration from the duplicate sample:

$$\mathrm{RPD}\,(\%) = \frac{x - y}{(x + y)/2} \times 100$$

Reproducibility was excellent at concentrations greater than ten times the limit of detection (LOD) for the ICP scans and greater than 1% for the QEMSCAN duplicate. The RPD criterion does not apply at concentrations near the LOD because RPD is expected to frequently be greater than 25% due to reduced analytical accuracy at very low concentrations. The only exceedances of the 25% RPD criteria were for the ST18-02-01 and ST18-02-02 duplicate set: vanadium was 224 and 292 mg/kg, respectively (RPD 26%), and the ST05-02-01 and ST05-02-02 duplicate set: moisture content was 19 and 28%, respectively (RPD 39%).

5.2.3 Blanks

Silica sand blanks submitted as ‘blind’ samples were assessed with respect to ten times the limit of analytical detection. Based on this criterion, the majority of elements for all three samples were below this level. A few elements exceeded this criterion (Ce, Cu, Fe, La, Pb, Mn, Ni, Rb, Ag, Sr, and Y), but only marginally so by ten to fifteen times detection limits. Concentrations were orders of magnitude lower than the concentrations in the samples.

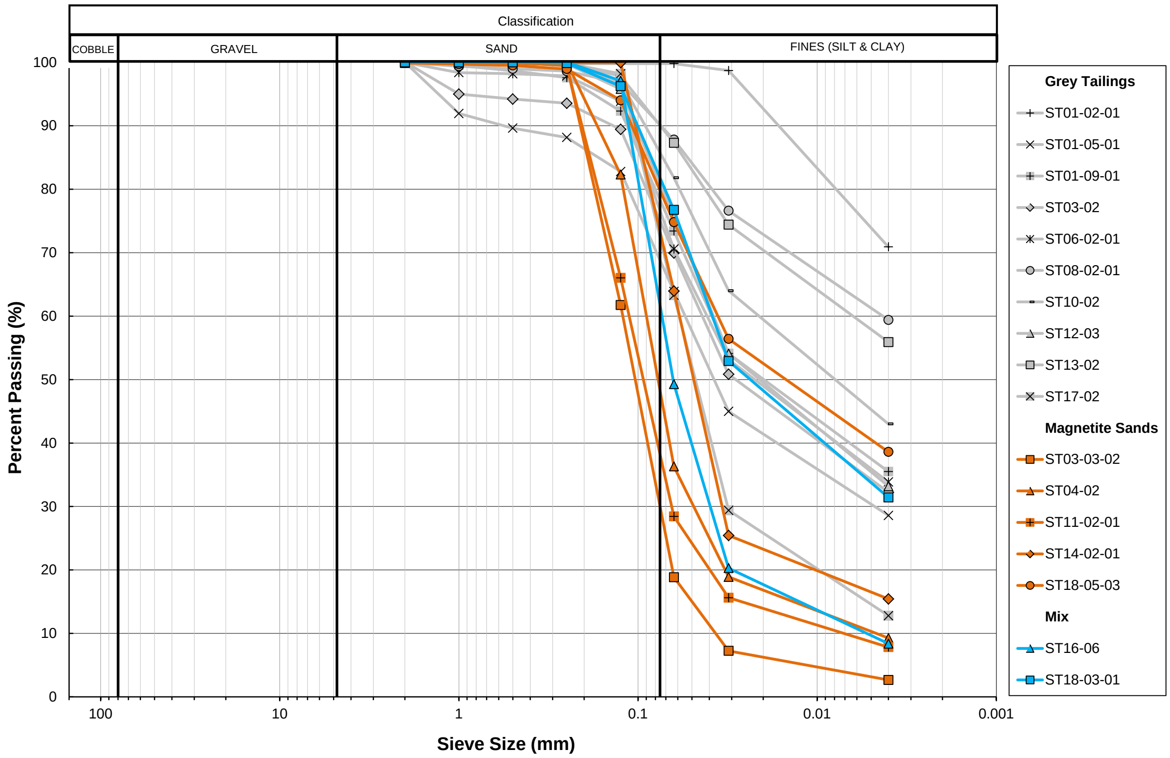
5.3 Assessment of Sampling Spatial Variability

Spatial variability was assessed for the Hazeltine Creek tailings samples based on 5 replicates taken 1 m away from the original samples (Appendix C3). Generally, the replicates were very similar to the original samples with average RPDs of less than 10%. However, some local variability was discovered as the ST06-04-01 and ST06-04-02 replicate set had an average RPD of 29% with 30 out of 55 parameters having RPDs greater than 25%. This higher variability may reflect various degrees of mixing between the tailings and native sediments during deposition.

SRK’s overall conclusion based on the above results was that the composites collected as part of this study captured the range of variability in the near vicinity (i.e. metres) of where they were collected. Variability of the samples collected downstream and generally as part of this study is discussed in Sections 5.3.

5.4 Particle Size Distribution

Particle size data for the Hazeltine Creek tailings samples are provided in Appendix C4 and illustrated in (Figure 5-1). Particle size distributions were largely bi-modal, consistent with textural observations in the field. The magnetite sands tailings samples generally contained less silts and clay-sized particles than the grey tailings samples, with the exception of one sample (ST18-05-03).



Z:\01_SITES\Mt_Polley\1CI008.003_Privileged_and_Confidential\500_Reporting\Interpretations\Geochemistry\Hzltn_Crk_2014\[MtPolley_HzltnCrk_2014_1CI008.003_REV00_CBK.xlsx]

Figure 5-1: Hazeltine Creek tailings particle size distribution results.

5.5 Acid Base Accounting

Acid-base accounting data for the Hazeltine Creek tailings samples are provided in Appendix C5. A summary of findings is provided in the following sections.

5.5.1 Sulphur Forms and Acid Potential

A statistical summary of total sulphur results determined by aqua regia digestion and ICP-MS is provided in Table 5-1. Sulphur ranged from 0.1 to 0.3%, with an average of 0.2% for all samples. These values are considered relatively low compared to other mine sites and consistent with the geological setting (MEND 2009). The results were fairly consistent by material type, with the magnetite sands containing more sulphur than the grey tailings with average values of 0.2 and 0.1%, respectively (significant difference based on a one-tailed t-test, $p < 0.05$).

Total sulphur content was also determined by the LECO furnace method for all of the samples that were selected for Phase 2 analyses. The LECO sulphur and ICP-MS sulphur results were similar (Figure 5-2). The concentration of sulphur in many of the samples was within ten times the limit of detection (i.e. 0.1%) and variability in the results is attributed to analytical uncertainty. Sulphate sulphur analysis by HCl leach also indicate that sulphate results were near or below the LOD (0.01%) and as organic sulphur in tailings is expected to be negligible, sulphide sulphur from ICP-MS analysis was set to equal total sulphur for the basis of acid potential (AP) calculations.

Acid potential was calculated using total sulphur content from ICP-MS as:

$$AP = \text{Total Sulphur} \times 31.25$$

where AP is expressed in kg $CaCO_3$/t and total sulphur is expressed in %.

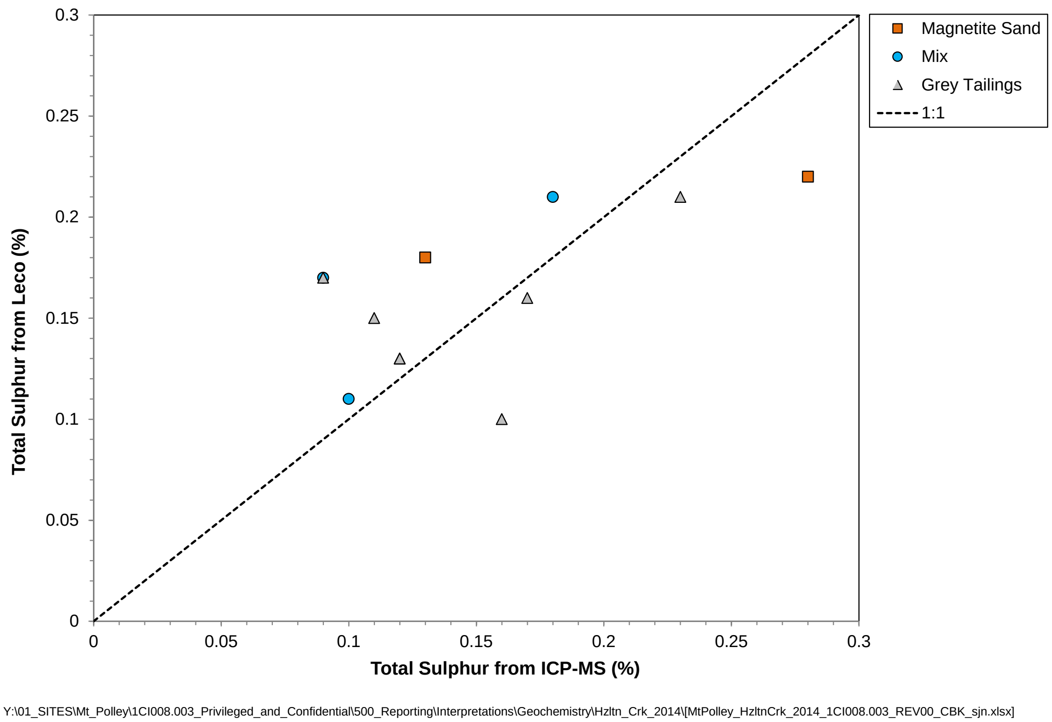


Figure 5-2: Hazeltine Creek tailings LECO vs. ICP-MS Sulphur

5.5.2 Neutralization Potential

A statistical summary of carbonate neutralization potential (NP) results is provided in Table 5-1. Carbonate NP, measured as total inorganic carbon (TIC), ranged from 8.7 to 40 kg $CaCO_3$/t with an average value of 27 kg $CaCO_3$/t for all Hazeltine Creek tailings samples. The results were fairly consistent by material type, with average TIC reported for the grey tailings being greater than for the magnetite sands tailings, although the averages were not statistically different based on a two-tailed t-test ($p < 0.08$). The grey tailings contained an average of 28 kg $CaCO_3$/t, whereas the magnetite sands contained 24 kg $CaCO_3$/t.

Modified Sobek NP results are available for all samples that were selected for Phase 2 analyses. Modified NP was generally greater than carbonate NP (Figure 5-3), which may indicate the presence of reactive silicate minerals in the test, or residual lime in the samples (a processing reagent added in the mill), or both. Silicates provide neutralization under the conditions created for the Modified Sobek NP analysis, but their reactivity is low and they generally do not contribute to neutralization under field conditions. Lime would also react in the modified NP titration test but not contribute to carbonate content. Consequently, carbonate is a better measurement of NP for the Hazeltine Creek tailings and was used for the ARD assessment.

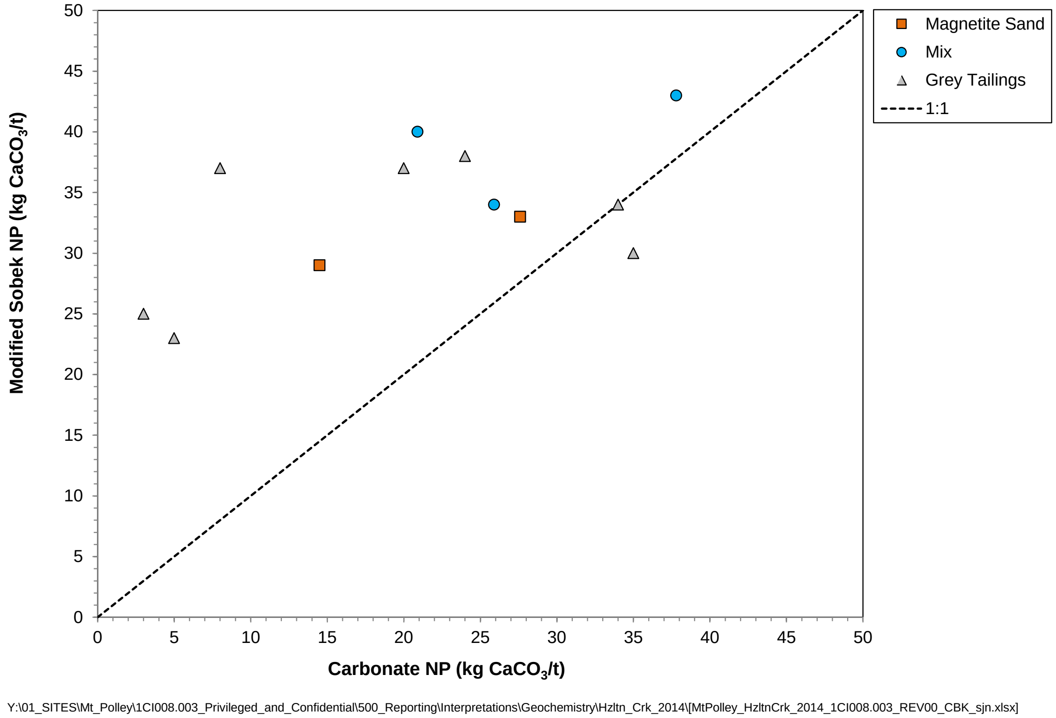

Figure 5-3: Hazeltine Creek tailings Modified NP vs. Carbonate NP

Table 5-1: Statistical summary of tailings samples geochemistry results from Phase 1.

Note: Results have been rounded to two significant figures.

5.5.3 Acid Rock Drainage Potential

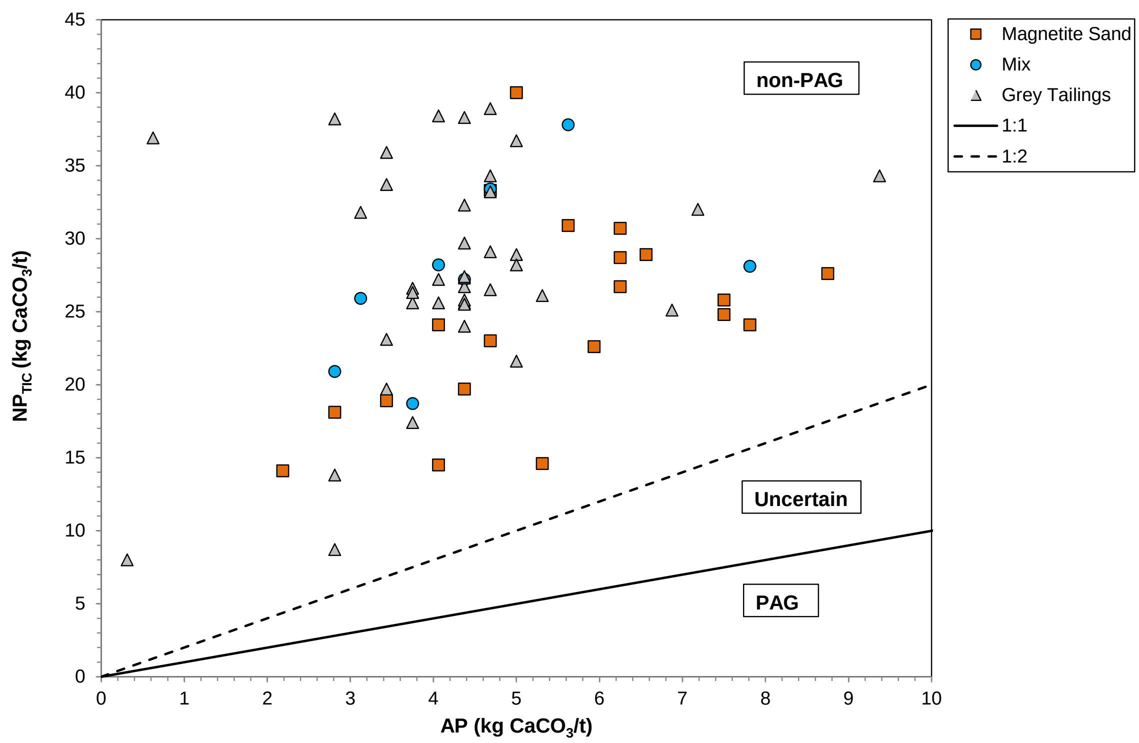
Acid rock drainage (ARD) potential was assessed based on neutralization potential ratios (NPRs) calculated as:

$$NPR = \frac{\text{Carbonate NP}}{AP}$$

Carbonate NP in the above equation is based on TIC as described in Section 5.5.2.

In this ARD assessment, NPR below 1 indicates potential for ARD (PAG – potentially ARD generating), NPR above 2 indicates low potential for ARD (non-PAG), and NPR between 1 and 2 indicates uncertainty. The NPR value of 2 was used to define non-PAG as calcite (refer to Section 5.8.1), which was found to be the predominant carbonate present (MEND 2009). A statistical summary of the NPRs for the Hazeltine Creek tailings samples is provided in Table 5-1.

All of the samples were classified as non-PAG, with NPRs as high as 59 (Figure 5-4). By material type the magnetite sands had slightly lower NPRs, mainly due to marginally lower carbonate content. Overall, the potential for ARD from the tailings in Hazeltine Creek is very low.

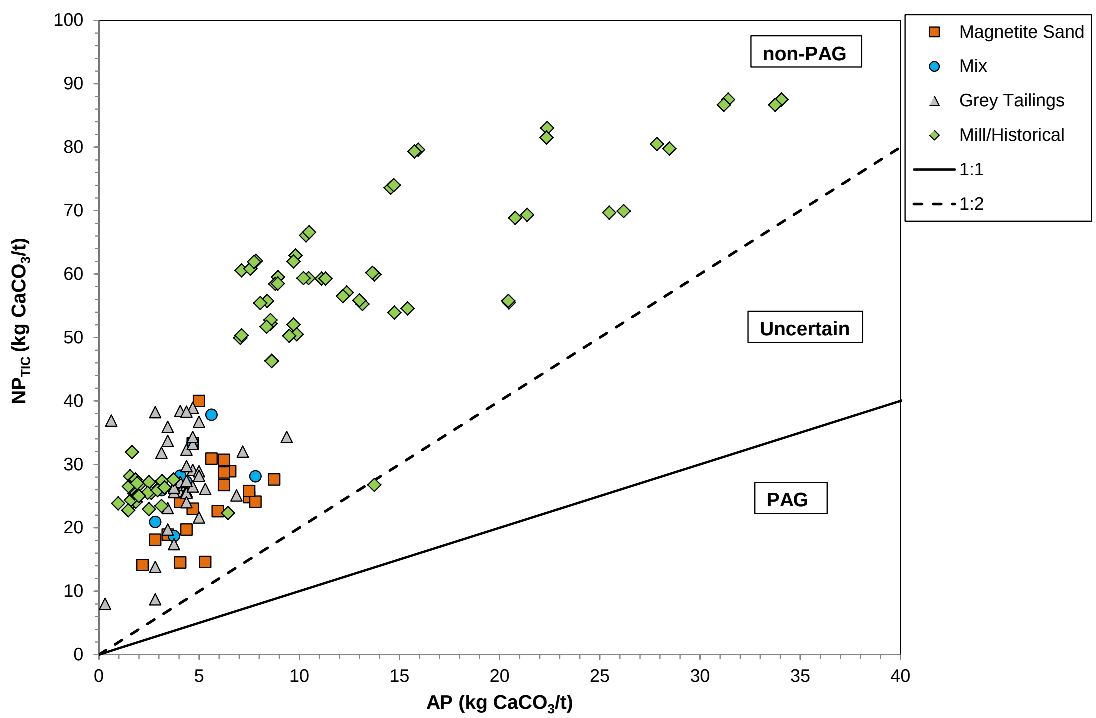


Z:\01_SITES\Mt_Polley\1CI008.003_Privileged_and_Confidential\500_Reporting\Interpretations\Geochemistry\Hzltn_Crk_2014\[MtPolley_HzltnCrk_2014_1CI008.003_REV01_CBK sin.xlsx]

Figure 5-4: ARD potential of Hazeltine Creek tailings.

5.5.4 ARD Comparison to Operational Tailings

Historical data provided by MPMC to the BC MOE (http://www.env.gov.bc.ca/eemp/incidents/2014/mount-polley.htm) provides a basis to compare ARD characterization results obtained from this study to characteristics from operational/historical tailings collected over the life of mine from the mill. Results of the comparison are provided in Figure 5-5 and show that none of the samples collected to date are PAG and only one sample in the dataset was on the boundary between non-PAG and uncertain. The samples containing higher NP and AP are all predominantly from mining between 2006 and 2008, whereas samples after this time contain very similar NP and AP values to the samples collected from Hazeltine Creek. The lower AP and NP values in samples from along Hazeltine Creek may also reflect tailings that have been mixed with native sediments that contain lower amounts of sulphur and carbonate than the tailings.



Z:\01_SITES\Mt_Polley\1CI008.003_Privileged_and_Confidential\500_Reporting\Interpretations\Geochemistry\Hzltn_Crk_2014\[MtPolley_HzltnCrk_2014_1CI008.003_REV01_CBK_sin.xlsx]

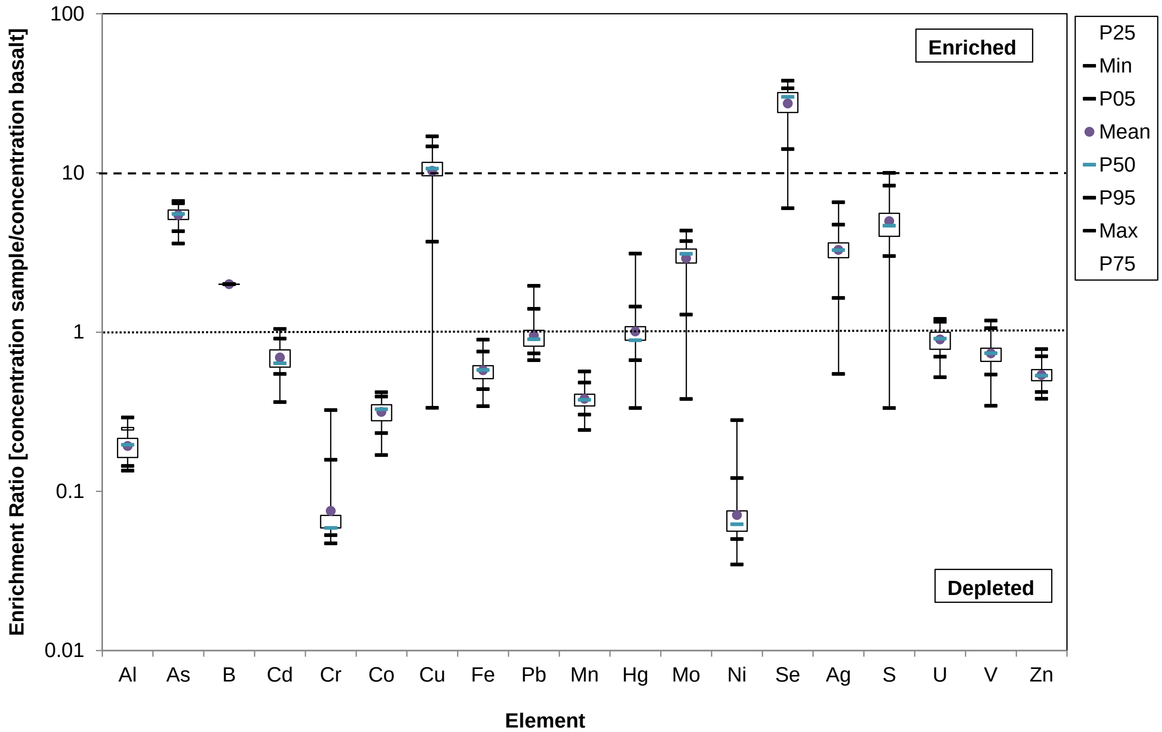
5.6 Trace Element Occurrence

5.6.1 Element Enrichment

Complete analytical composition results from a 35 element scan are provided in Appendix C6. For ease of reference a shortened list of element concentrations that have guidelines for the protection of freshwater aquatic life in British Columbia is provided in Table 5-1.

To provide an indication of trace element enrichment in the spilled tailings samples, concentrations were compared to typical global average concentrations for basalt (Price 1997). This comparison approach is a standard element leaching screening practice as outlined by MEND (2009).

Concentrations present at more than an order-of-magnitude above global average values were considered enriched for the purpose of screening and enrichment ratios are shown in Figure 5-6. The ratios were calculated by dividing the concentration of copper (for example) in the sample by the typical concentration of copper in basalt. Ratios greater than 10 are considered enriched. Ratios less than one indicate lower concentrations in the Hazeltine Creek samples than in average basalt. ‘Box and whisker’ plots were used to illustrate the results, with the boxes representing the 25th to 75th percentile ranges. The solid horizontal line represents equivalence with typical basalt, whereas the dashed line represents ten times the concentration of basalt.



Z:\01_SITES\Mt_Polley\1CI008.003_Privileged_and_Confidential\500_Reporting\Interpretations\Geochemistry\Hzltn_Crk_2014\[MtPolley_HzltnCrk_2014_1CI008.003_REV00_CBK.xlsx]

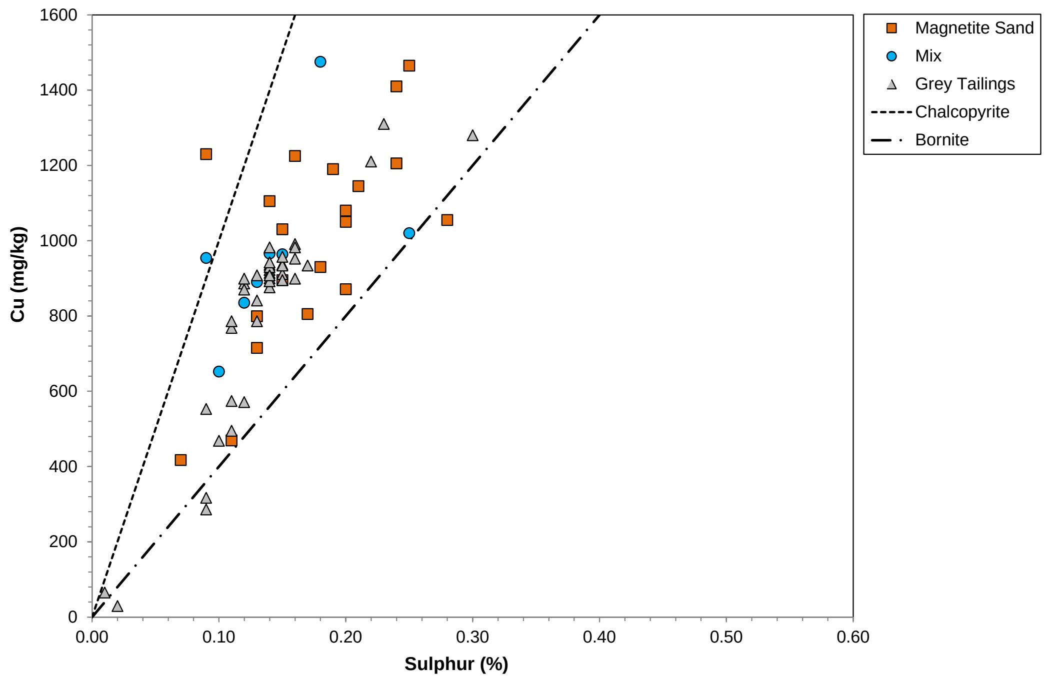
Figure 5-6: Element enrichment assessment for Hazeltine Creek tailings samples.

By this method, copper and selenium are considered to be enriched in the tailings. The magnetite sands contain more copper than the grey tailings, with average values of 985 and 812 mg/kg, respectively. The difference between the averages is statistically significant based on a one-tailed t-test ($p < 0.05$). The average selenium concentrations for both tailings types were statistically the same at 1.4 mg/kg.

Despite the ‘enrichment’ noted in the spilled materials, the average concentration of selenium in operational tailings from within the TSF is lower (1.1 mg/kg) than the spilled materials and similar to the average of 137 regional stream sediment samples from the region surrounding Mount Polley (average 1.0 ppm, range 0.1 to 9.1 ppm)(GSC 1981; Jackman 2008). This is important to note as the screening was done for the purposes of geochemical characterization, which concerns itself with the likelihood of chemical release mechanisms. However, the presence of a possible release mechanism should not be inferred to mean that a release of metals or others elements would give rise to adverse environmental effects. The human and ecological risk assessment, planned for the summer of 2015, will evaluate this potential. This is a relevant distinction in the present case because selenium is identified to be enriched in this geochemical evaluation but is present in the tailings at concentrations that are less than the Urban Park Land Use standard (PL; 3 mg/kg), which is used as a soil quality benchmark as it is considered appropriate as a screening tool for sites in a wildlands land use setting.

5.6.2 Element-Mineral Correlations

The correlations between copper and sulphur, selenium and sulphur, and selenium and copper are provided in Figure 5-7, Figure 5-8, and Figure 5-9, respectively. Correlation of copper and sulphur ($r = 0.78$) indicate that copper is likely associated with chalcopyrite and bornite, although it could also be copper-enriched pyrite. The chalcopyrite and bornite correlation is consistent with previous estimations of ore mineralogy (Henry, 2009). With regards to selenium, there is a better correlation between selenium and copper ($r = 0.68$) than between selenium and sulphur ($r = 0.54$), which may indicate that selenium is preferentially associated with the copper sulphide rather than pyrite. All of the correlations were significant at the 99% confidence level indicating that both copper and selenium are probably associated with sulphur (sulphide) which is expected from the elemental properties of selenium.



Z:\01_SITES\Mt_Polley\1CI008.003_Privileged_and_Confidential\500_Reporting\Interpretations\Geochemistry\Hzltn_Crk_2014\[MtPolley_HzltnCrk_2014_1CI008.003_REV01_CBK_sjn.xlsx]

Figure 5-9: Comparison of selenium and copper for Hazeltine Creek tailings samples.

5.6.3 Element Trends in Hazeltine Creek Tailings Deposits

Trace element concentrations were also evaluated in terms of distance from the tailings dam failure in order to determine if spatial considerations for element leaching needed to be evaluated. Concentrations were correlated with distance down Hazeltine Creek, with transect ST17/18 serving as the starting location and distance calculated by the shortest distance downstream between each transect. For each transect (see Figure 4-1), results were averaged and Pearson's correlation coefficient was determined to evaluate the degree of linear dependence between concentration and distance.

Results for copper and selenium indicated that there was a statistically significant correlation at the 90% confidence limit (r = -0.45 and -0.41 for Cu and Se, respectively), indicating that concentrations decreased downstream. Results are provided in Figure 5-10 and Figure 5-11. Error bars on the graphs represent the range of concentrations measured in the samples along each transect. The sample at 6.5 km (ST4) only had one sample and so does not contain error bars, whereas at 2.5 km (ST12), error bars are smaller than the data point for selenium.

Only copper and selenium are presented as they were the only elements identified as exceeding the enrichment criteria (i.e. ten times crustal basalt concentration). When compared to the criteria downstream, copper fluctuated above and below the enrichment criteria, but remained below for the last three transects closest to Quesnel Lake. Selenium was always above the enrichment criterion.

Figure 5-11: Comparison of tailings selenium concentration by distance downstream.

Based on the results of the comparison from available results to date, the element concentration changes observed downstream are not significant enough that consideration of element leaching potential by distance from the dam failure is warranted.

5.6.4 Trace Element Comparison to Operational Tailings and Regional Sediments

Historical data provided by MPMC to the BC MOE (http://www.env.gov.bc.ca/eemp/incidents/2014/mount-polley.htm), in addition to previous studies by the Geological Survey of Canada and Geoscience BC, provides a basis to compare element concentrations determined in this study to characteristics from operational/historical tailings collected over the life of mine from the mill and regional sediments collected in the 1980s prior to mining the Mount Polley deposit. Carbonate (NP) and sulphur (AP) were compared in Section 5.5.4, so copper and selenium are the only elements compared here given that it is only these two elements that were found to be enriched in the tailings.

The average copper concentrations were similar for the spilled tailings and the operational tailings at 890 mg/kg versus 1050 mg/kg, respectively (Figure 5-12). However, based on a one-tailed t-test the means were statistically different (p level equal to 0.01). The spilled tailings also had a lower range reported, although copper concentrations in the tailings during the first few years of mining were reported as being nearly double the last ten years (Figure 5-12), which has likely biased the average high. Mixing with native sediments during deposition would also likely lower the concentration of the materials sampled from along the creek as the native sediments had an average copper concentration of 50 mg/kg and ranged from 4.5 to 780 mg/kg (GSC 1981; Jackman 2008) (Figure 5-12). As a result, the difference between the two datasets is attributed to an averaging effect and potentially mixing rather than non-homogeneity or “hot spot” phenomena.

The average selenium concentrations were also similar, but slightly higher in the spilled tailings as compared to the operational mill tailings at 1.4 mg/kg and 1.0 mg/kg, respectively (Figure 5-12). The means were statistically different based on a one-tailed t-test and while the range was higher in the mill tailings (Figure 5-12), overall the concentration of selenium appears to be well represented in the creek samples. The slightly higher average in the creek samples could be due to a number of selenium concentrations not being reported in earlier mill tailings samples as detection limits have decreased over time, but could also be due to the native sediments that have mixed with the tailings during deposition having higher selenium concentrations than the tailings (Figure 5-12)(Jackman 2008).

5.7 Kinetic Testing and Copper Oxide Analysis

Kinetic testing is being performed to assess empirical weathering rates of the spilled tailings along Hazeltine Creek, which will also help refine element leaching potential beyond the initial screening test. At the time of preparation of this report, only three cycles of results (representing 6 weeks of testing) for the humidity cells had been received and no data for the columns were available. As mentioned previously, these tests are typically run for a minimum of 40 weeks and meaningful results are usually not available until after at least 20 weeks. Kinetic testing results will be provided in an update report once the tests have stabilized and a more substantial number of cycles have been completed.

Non-sulphide copper analyses (also referred to as copper oxide) were also not available at the time of this report and will also be reported subsequently. These results will help confirm the amount of copper and other trace elements that are associated with this marginally soluble mineral fraction.

5.8 Mineralogy

5.8.1 General Composition

Minerals detected by QEMSCAN and electron microprobe are shown in Table 5-2 and X-ray diffraction results are provided in Table 5-3. Complete mineralogy results are provided in Appendix C7 and Appendix C8.

The samples are dominated by silicates, including feldspars, chlorite and quartz. Chrysocolla was noted, although only at trace levels. Iron oxides (magnetite and hematite) were frequently the next most abundant minerals after the silicates, followed by carbonates and the minor amounts of sulphides. The presence of quartz at concentrations greater than 1% is a good indication that the tailings are intermixed with native sediments as the deposit is syenitic to monzonitic and the tailings should contain very little to no quartz (BC MINFILE No. 093A 008).

Sulphide mineralogy is consistent with the ore mineralogy previously described for the project, including pyrite and chalcopyrite as the two main sulphide minerals in approximately equal proportions (approximately 0.2% for each mineral), followed by bornite (less than 0.1%) and other copper sulphides (likely covellite). Typically XRD has higher detection limits than QEMSCAN, which is why the sulphides have not been reported by XRD.

The main carbonate present was calcite, ranging from 0.7% to 4.5%. Dolomite was also present, although typically less than 0.1% with the exception of one sample (HC-4) at 0.4%. Malachite was also present, although at near detection levels and at much lower concentrations than expected based on previous understanding of the ore (Section 2.1).

Iron oxides present ranged from approximately 3 to 7%. QEMSCAN is a composition based technique (i.e. all iron oxides will be noted together) and differentiation of individual iron oxides was performed on three samples using XRD, which identifies minerals based on structure. Magnetite was found to be the main iron oxide present, which is consistent with visual observations in the field and sequential leaching results (Section 5.9). Hematite was also present, but at less than 50% of the total iron oxide abundance in the samples tested. In the 'Magnetite Sand' sample, magnetite comprised approximately 75% of the iron oxide detected.

Note: '-' denotes that the mineral was not detected.

5.8.2 Mineral Exposure

The degree of mineral exposure (also referred to as liberation) was measured by QEMSCAN for the sulphides and carbonates. This is a useful characteristic to understand as the more a mineral is exposed to its surrounding environment (e.g. the atmosphere and precipitation), the more susceptible it likely is to weathering. Conversely, the less exposed a mineral, the less likely it is susceptible to weathering.

Analytical results are provided in Appendix C7. As tailings are the product of grinding activities, mineral liberation is expected to be high. This was true for the carbonate minerals, ranging from approximately 30% to 80% of the carbonates fully exposed. However, the iron sulphides were variably less exposed. With the exception of HC-3 (a grey tailings sample), sulphides were predominantly locked, with over 50% of the minerals less than 10% exposed. It is noted that quantification for the sulphides is expected to be somewhat uncertain due to the relatively low amounts of sulphide present (i.e. < 1%).

5.8.3 Mineral Deportment of Copper and Selenium

Deportment can be considered assignment of which mineral 'hosts' a particular element. This is important for understanding reactivity of the tailings, as if an element is 'deported' entirely to a water soluble mineral, then dissolution processes will control its release. However, if an element is deported to sulphide mineral, then oxidation will be the mechanism that controls release.

The deportment of copper and selenium was investigated. However, the concentration of selenium was too low to be detected by QEMSCAN or electron microprobe (typically around 0.1%, whereas the concentration in the samples is only 0.0001%). Consequently, only the results for copper are discussed below.

Copper mineral deportment results are provided in Figure 5-13 and complete analytical results are provided in Appendix C7. Chalcopyrite contained approximately half of the copper when total copper concentrations were above 0.05%. Chlorite was the next most abundant mineral to host copper, followed by bornite and covellite/chalcocite. Malachite was not detected as a significant mineral host for copper. The deportment in chlorite was unexpected as previous investigations have indicated that chrysocolla was the non-sulphide mineral phase hosting copper. However, other studies have also noted the same finding (Chanquıa et al, 2010) and the overall implication is likely insignificant as previous work by MPMC has shown copper in the non-sulphide phase extremely resistant to leaching by acidic solutions (Taplin 2002; Henry 2009).

Based on the mineral characterization and element deportment work, the copper mineral inventory in the spilled tailings samples is composed of a mixture of sulphides with a significant portion in slowly weathering silicates. Given the correlation identified between selenium and copper (Section 5.6.2), selenium can also be reasonably assumed to be present in at least the sulphide mineral forms. While some variation among the samples exists, based on the mineralogy results, leaching of copper and selenium will require oxidation in a subaerial environment. This is discussed further in Section 6.1.

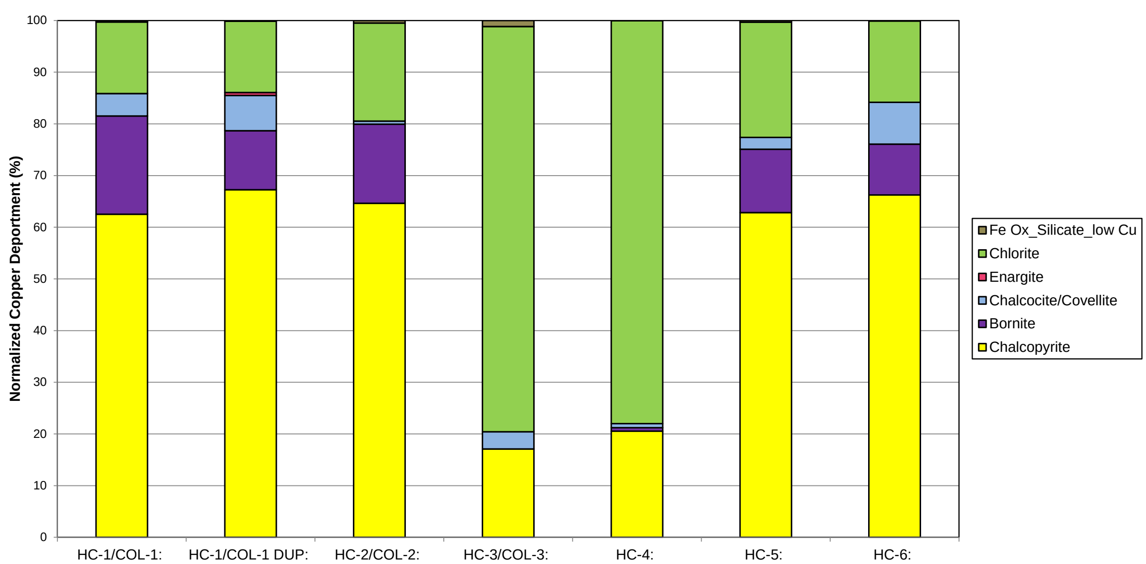

Figure 5-13: Mineral deportment of copper.

5.9 Sequential Extraction Results

5.9.1 Minnow Environmental Results

Complete results from sequential extraction testing are provided in Appendix D.

Results from the extractions were grouped together to represent spilled tailings from Hazeltine Creek, from the bottom of Quesnel and Polley Lake, and also lake sediments that were not impacted by the tailings discharge (i.e. a background lake reference). The groupings also provide the context to compare and discuss implications of the new depositional environment of the tailings in terms of the profundal zone (i.e. the deepest part of the lake) where reducing conditions could develop.

Sulphur results were not included in the analysis, and so iron was used to help understand major mineralogy, followed by copper and selenium on account of their enrichment as compared to global basalt averages. Arsenic is also presented as it is often an element that is sequestered by iron oxides and susceptible to reductive dissolution, although it should be noted that arsenic was not considered enriched in the MPM tailings samples.

Iron was predominantly associated with the ‘residual metals’ fraction (e.g. 85% of total iron extracted in lake tailings) in all samples tested, which as described in Section 4.3.5, is likely comprised of mainly sulphides due to the use of an aqua regia digest (Figure 5-14). Magnetite, hematite and some silicates may also be partially digested in this fraction, but only marginally as aqua regia on sieved, not pulverized, samples will not result in a complete digestion. Iron oxides are likely a small portion of the samples as only a minor portion of the iron was present in the reducible fraction (12% of total) and at lower average concentrations than present in the lake reference sample. When compared to the lake reference sample, the average ‘reducible’ iron fraction was greater in the lake reference than the tailings samples and a statistical analysis (t-test) showed that the reducible iron oxide concentrations in Quesnel Lake tailings were not significantly different than the background samples.

Arsenic was also predominantly associated with the ‘residual’ fraction and not with reducible iron oxides (71% versus 17%, respectively) (Figure 5-14). This is consistent with arsenic being present in a sulphide mineral phase. When compared to the lake reference sample, arsenic was also predominantly associated with the ‘residual’ fraction at 71% in the lake reference sample. The lake tailings ‘reducible’ phase had slightly higher arsenic content than the lake reference sample that was statistically different based on a t-test, although results were relatively low for both samples when compared to the total available arsenic in these samples.

Copper was primarily associated with the ‘organic bound’ metal fraction in the tailings, ranging from 63% to 56% in the creek and lake tailings, respectively (Figure 5-14). As discussed in Section 4.3.5, this is likely partially associated with sulphide minerals and also chlorite due to the reagents and temperatures used in the extraction step (Tessier 1979). Mineralogy results presented in Section 5.8 also support this with the deportment of copper partially in chlorite. The ‘residual’ fraction contained the next highest amount, but also notable for copper was the presence of 4% in the ‘carbonate metal’, likely reflecting the presence of malachite. When compared to the lake reference sample, total copper was two orders of magnitude lower and the highest proportion of copper was in the ‘residual’ fraction for the lake reference samples.

Selenium was similar to copper in that it was also primarily associated with the ‘organic bound’ metal fraction, ranging from 33% to 46% in the creek and lake tailings, which as noted above likely represents sulphide minerals and also the copper silicate. This is consistent with element scan correlations in that selenium appears to be associated with the copper sulphides. Selenium was below detection in the other fractions as 0.2 mg/kg is the calculated detection limit based on aqueous concentrations in the sequential extraction tests (does not include water extractable). The one exception was the creek tailings ‘residual metals’ fraction as this sample was slightly above analytical detection limits. When compared to the lake reference sample, selenium was also highest in the ‘organic’ fraction, at 27% of the total. Statistical analysis (t-test assuming unequal variances) showed that the ‘organic’ fraction of selenium was not different between the tailings and lake reference sample.

5.9.2 Comparison between Datasets

Copper and selenium concentrations in the samples collected by SRK and SNC-Lavalin with Minnow Environmental data were compared to check that the element partitioning interpretations based on the Minnow Environmental results were broadly applicable.

Results of the comparison are provided in Figure 5-15 and Figure 5-16, and show that the SRK/SNC averages were higher for copper and lower for selenium, with significant overlap between the majority of samples. The differences for copper and selenium are likely a result of greater mixing with native sediments than the samples along Hazeltine Creek. This is because the selenium concentrations in native sediments are similar or higher when compared to the tailings, whereas copper concentrations are lower in the sediments (Figure 5-12; GSC 1981; Jackaman 2008; Minnow 2014). Thus, the higher selenium and lower copper contents of the Lake Polley samples indicates that there could have been more mixing in Polley Lake as compared to the spilled tailings collected along Hazeltine Creek and Quesnel Lake.

The difference in selenium between the samples collected by SRK and Minnow Environmental may also be partially attributed to the manner in which concentrations for the Minnow Environmental samples were calculated. For each of the sequential extraction steps, the total amount of selenium was summed, including detection limits at the level of detection (0.2 mg/kg). As a result, up to an additional 0.8 mg/kg (from four below detection limit results) of selenium could have been added to the total, or approximately 25% of the total amount of selenium reported.

Based on the comparison of the available data, SRK's conclusion is that the sequential extractions were performed on a range of sample compositions and are broadly applicable for making interpretations in this study. There is also nothing in the dataset or understanding of ore mineralogy to indicate that higher copper or selenium concentrations would be in mineral forms not identified in this study.

6 Discussion

6.1 General Element Leaching Concepts

6.1.1 Overview

The geochemical characterization program outlined here was developed to provide information on the potential for release of metals or other elements from the spilled tailings. The initial geochemical conceptual model provided the framework to evaluate spilled tailings reactivity impacts as follows:

- Representative sample collection.
- Subaerial weathering of tailings along Hazeltine Creek.
- Subaqueous dissolution in the profundal zones of Polley Lake and Quesnel Lakes.

The main pathway for water quality impacts on the Hazeltine Creek tailings is neutral pH weathering. ARD has not been identified as a concern for tailings historically and the results of this program confirm the previous findings. As a result, leaching considerations are focused on neutral pH conditions.

Considerations for leaching of water-saturated tailings along the bottom of Hazeltine Creek are also not considered further. This is because this region of the stream likely remains aerobic and leaching from the spilled tailings would effectively be inhibited.

6.1.2 Representative Sample Collection

Tailings were deposited along an approximately 8 km reach down Hazeltine Creek. Therefore, it was appropriate to understand the range of variability in tailings chemistry along the Creek to determine if conclusions regarding geochemistry in one area of the Creek could be applied to other areas of the Creek.

Based on: i) the TSF deposition history of the tailings, ii) comparisons of ML/ARD potential between the creek tailings and operational mill tailings, and (iii) the distribution of samples analyzed, it is likely that the possible range of geochemical characteristics of the spilled tailings were suitably characterized by this program. All of the highest sulphur, carbonate and copper concentrations appear to be from the initial years of mining and do not appear to have left the impoundment. SRK concludes that the interpretations and implications based on the samples collected for this study are applicable to the entire impacted area.

6.1.3 Subaerial Weathering of Tailings

The spilled tailings and mixed in sediment materials stored along the banks of Hazeltine Creek and any other subaerial setting will weather in the presence of oxygen. However, leaching is expected to be slow because sulphides containing copper and selenium leach at relatively slow rates under neutral pH conditions. On-going geochemical testing is establishing these rates. Silicates will also weather, but at even slower rates that are dependent on mildly acidic rainwater (the dissolved carbon dioxide equilibrium pH of rainwater is ~5.5). Given the carbonates present in the MPM tailings, mildly acidic rainwater will be neutralized upon contact and leaching of silicates would be slower than could occur by rainwater. Specific leaching rates for the tailings collected are currently being established through kinetic testing and will be reported subsequently.

Copper was identified as an enriched element, but this is consistent with the nature of the copper porphyry deposit that the MPM was mining. A significant portion of the copper has previously been reported in two site specific studies to be locked up in a non-sulphide mineral that required extremely acidic conditions (i.e. 25% HCl solution) to leach (Taplin 2002; Henry 2009). This study has found that the non-sulphide associate mineral is chlorite and likely ranges from 20% to nearly 70% (Figure 2-1) of the total copper in the spilled tailings, which effectively lowers the total leachable copper content. For example, if only 20% of the copper is locked up in silicates, then this would bring the sulphide associated oxidizable copper down from the average of approximately 1,000 mg/kg to 800 mg/kg, which is below the enrichment criteria.

Thermodynamic first principles and the equilibrium modelling software package PHREEQC (version 2.17.4137) (Parkhurst and Appelo, 1999) predicts low solubility of copper at neutral pH as compared to concentrations that are associated with copper porphyries under acidic pH (Day and Rees, 2006). This is because secondary copper oxide minerals that would form after oxidative dissolution from a copper sulphide are only sparingly soluble. The prediction by PHREEQC under aerobic conditions and carbonate buffered rainwater is an upper limit of 0.02 mg/L due to copper oxide solubility limits. This is consistent with other copper concentrations measured under neutral pH at the MPM and other copper porphyry sites (Day and Rees, 2006).

Selenium was shown to be correlated with copper and likely is present as an accessory element in the copper sulphides as this element often replaces sulphur owing to similar geochemical properties (Ralston et al, 2008; MEND 2015). However, the methods used in this study could not detect selenium co-precipitated with silicate minerals and so selenium release should be conservatively assumed to be associated only with oxidative dissolution of sulphides. Once selenium has been leached, it is also relatively soluble under oxidizing and neutral pH conditions and is unlikely to be controlled by mineral solubility (MEND 2015).

6.1.4 Subaqueous Dissolution of Tailings

For any of the spilled tailings that ended up in Quesnel or Polley Lake, water saturation is the best way to inhibit oxidation of sulphides (INAP 2010). Therefore, leaching of any elements hosted in sulphides (i.e. copper and selenium) that would be released by oxidation is effectively inhibited for tailings present in Quesnel and Polley Lakes.

The settling of spilled tailings deep in Quesnel or Polley Lake could be susceptible to reductive dissolution processes. This is because certain minerals like iron oxyhydroxides (i.e. ferrihydrite) contain ferric iron that is only sparingly soluble under aerobic neutral pH conditions, but becomes much more soluble if converted to ferrous iron by iron reducing bacteria in anaerobic environments (Lovely 1991). Ferrihydrite is a well-known mineral for sorbing other elements and if it undergoes reduction dissolution, then those elements could also potentially become soluble.

Based on the results of the mineralogical characterization work and sequential extractions, the risk for mobilization of elements under reducing conditions is very low. Easily reducible iron oxides were minor components of the tailings samples tested and neither copper nor selenium were associated with a mineral phase that would be susceptible to reductive dissolution. Arsenic was also evaluated as it is often sorbed to iron oxyhydroxides, but it was primarily associated with sulphides.

It should also be noted that selenium behaves quite differently under reducing conditions and will either sorb to mineral surfaces if it is speciated as selenite, or precipitate as elemental selenium (Ralston et al, 2008; MEND 2015). In either event, even if selenium was released from reductive dissolution processes, its geochemical behaviour under reducing conditions would result in it being removed from the water column and it is not considered a water quality risk under subaqueous reducing conditions.

7 Conclusions and Next Steps

Geochemical characterization, including ABA tests, trace element analyses, mineralogical analyses, and sequential extractions have been undertaken on representative tailings samples that spilled into Hazeltine Creek, and Quesnel and Polley Lakes from the MPM.

The results indicate that the MPM tailings are not potentially acid generating, which is consistent with historical understanding of the tailings and the low sulphur nature of the ore deposit. Leaching considerations are under neutral pH only, which tends to support low mineral and element specific solubility. The only elements that were noted to be enriched when compared to typical crustal rocks (basalt) were copper and selenium. Both of these elements were primarily associated with sulphide minerals and require oxidation to be leached. The potential for reductive dissolution processes to leach elements from the spilled tailings that have settled in Quesnel and Polley Lakes was assessed and found to be low.

Copper is partially deported to silicate minerals and is also relatively insoluble at neutral pH. Therefore, it is not considered to be readily leachable from the spilled tailings. Selenium appears to only be associated with the sulphide fraction, is soluble at neutral pH, and will be leached to a small degree from the tailings when located in a subaerial environment. However, given the relatively thin deposition of tailings along the creek and high dilution potential from precipitation and other sources, selenium concentrations are likely to be low.

Kinetic testing of the samples using humidity cells and columns is on-going and will establish empirical weathering rates in the laboratory. The rates will need to be adjusted (geochemically ‘scaled’) to account for site temperature differences between the lab and field, but will provide a basis to further refine understanding of potential for water quality impacts from the spilled tailings. An update will be provided once stable leaching rates from the lab tests are available.

Executive Summary

Seven samples (six samples and one duplicate) collected from along Hazeltine Creek downstream of the tailings dam breach at the Mount Polley Mine, were submitted to the Advanced Mineralogy Facility by SRK on behalf of Imperial Metals Corporation. A mineralogical test program was conducted using QEMSCAN technology (Quantitative Evaluation of Materials by Scanning Electron Microscopy), X-ray Diffraction (XRD), Electron Microprobe Analysis (EMPA) and chemical analysis. The objective of this investigation was to determine the overall mineralogical characteristics with an emphasis on the sulphide and carbonate mineralization and to identify the mineral hosts of copper and selenium.

The as-received samples were wet screened at 2 mm. The work was conducted on the -2mm material while the +2 mm fraction was stored.

Sample Characteristics

The modal mineral abundances, sulphide and carbonate exposure along with size data of the samples are summarized in Table 1. Note that the exposure and size data is based on the as-received -2 mm fraction.

The sulphides (pyrite, chalcopyrite and bornite) range in abundance from 0.10% in HC-4 to 0.64% in HC-6, the carbonates (calcite and dolomite) from 1.15% in HC-4 to 4.50% in HC-6. Iron-oxides range from 2.84% in HC-4 to 6.97% in HC-1/COL-1. From the Rietveld XRD analysis, the iron oxides in HC-1/COL-1, HC-4 and HC-6 have been identified as magnetite (4.8%, 2.3% and 4.2% respectively) and hematite (1.7%, 2.2% and 1.7% respectively). The samples are primarily comprised of potassium-feldspar (24-43%), plagioclase (19-29%) and quartz ranging from 27% in HC-4 to 21% in HC-5.

Sulphides that have >20% exposure range from 12% in HC-6 to 66% in HC-3/COL-3, carbonates (>20% exposure) range from 62% in HC-6 to 93% in HC-3/COL-3.

The majority of the sulphides are <75 µm in size. Approximately 82% of the sulphide mass is <75 µm in size in HC-4 and 100% (88% are <30 µm) in HC-3/COL-3. The carbonates range in size. Thus, HC-3/COL-3 contains the finest in size carbonates with 100% at <75 µm, and HC-4 the coarsest with the majority (68%) of the carbonates at >75 µm and 32% at <75 µm.

Table 1: Summary Table of Sample Characteristics

Sample		HC-1/COL-1	HC-1/COL-1 DUP	HC-2/COL-2	HC-3/COL-3	HC-4	HC-5	HC-6

Elemental Deportment

The elemental deportment for copper (Cu) was calculated using EMPA averages and the QEMSCAN mineral distribution. The results are summarized in Table 2 (normalized values).

Selenium (Se) was found in four grains of bornite and could possibly be present in other minerals, but is below the detection limit of the electron microprobe.

Table 2: Elemental Deportment Summary (Normalized)

Element	Mineral Name	HC-1/COL-1	HC-1/COL-1 DUP	HC-2/COL-2	HC-3/COL-3	HC-4	HC-5	HC-6
Cu Deportment	Chalcopyrite	62.5	67.2	64.6	17.1	20.5	62.8	66.3

Introduction

This report describes a mineralogical test program using QEMSCAN technology (Quantitative Evaluation of Materials by Scanning Electron Microscopy), X-ray Diffraction (XRD), Electron Microprobe Analysis (EMPA), and chemical analysis on seven samples (six samples and one duplicate) submitted by SRK on behalf of Imperial Metals Corporation. The samples were collected along Hazeltine Creek, downstream of the tailings dam breach at the Mount Polley Mine. The objective of the test program was to determine the overall mineral assemblage with emphasis on the mineral exposure, particle size of the sulphides and carbonates, and the elemental deportment of copper and selenium.

Manager Metallurgy & Water Treatment

Sample Preparation: Juliet Khoshaba, Morgan Gibson-Wright
QEMSCAN Operation: Morgan Gibson-Wright
X-Ray Diffraction: Kim Gibbs, Huyun Zhou
Data Processing by: Sarah Prout
Report preparation by: Morgan Gibson-Wright
Report reviewed by: Sarah Prout, Cheryl Mina, Tassos Grammatikopoulos, Jake Lang

Testwork Summary

1. Sample Receipt, Preparation, and Analysis

Seven samples collected from along Hazeltine Creek, downstream of the tailings dam breach at the Mount Polley Mine, were submitted to the Advanced Mineralogy Facility by SRK on behalf of Imperial Metals Corporation. The shipment was assigned an internal sample receipt number of 0270-FEB15 and the project number CAVM-50220-103 was assigned to the testwork.

The as-received samples were inventoried (Table 3). Each sample was wet screened at 2 mm, with the mineralogical work carried out on the -2 mm fraction and the +2 mm fraction stored.

Table 3: Sample Inventory

Sample ID	-2 mm Wt (g)	QEMSCAN Analysis Mode
HC-1/COL-1	87.0	PMA and SMS
HC-1/COL-1 DUP	100.1	
HC-2/COL-2	81.0	
HC-3/COL-3	97.2	
HC-4	83.5	Field Scan (FS)
HC-5	98.3	
HC-6	97.1	

An assay cut was riffled and pulverized from each -2 mm sample, and submitted for whole rock analysis (WRA) by X-ray fluorescence (XRF). Additional chemical analysis data were provided by SRK on behalf of Imperial Metals Corporation including sulphur and copper. Approximately 10 g was riffled and pulverized from three of the samples (HC-1/COL-1, HC-4 and HC-6) and submitted for Rietveld X-Ray Diffraction (XRD).

Approximately 1 g sub-samples were micro-riffled from each -2 mm sample for polished section preparation. One graphite impregnated polished epoxy grain mount was prepared for each sample. Note: due to the coarse particle size, one polished section may not be representative of the whole sample, especially due to the low grade sulphide mineral occurrence; caution must be taken with interpretation of the data.

The polished sections were carbon coated and submitted for QEMSCAN analysis by Particle Mineral Analysis (PMA) and Specific Mineral Search (SMS) or the Field Scan (FS) mode of operation depending on the particle size, where the coarser samples (HC-4, HC-5 and HC-6) a FS analysis was used and for the finer (HC-1/COL-1, HC-COL-1 DUP, HC-2/COL-2 and HC-3/COL-3) samples a combination of PMA and SMS was used. Following the QEMSCAN analysis, the polished sections from samples HC-1/COL-1, HC-5 and HC-6 were submitted for Electron Microprobe Analysis (EMPA).

The certificates of chemical analysis are presented in Appendix A, the XRD report is presented in Appendix B, EMPA data is presented in Appendix C and additional QEMSCAN data is presented in Appendix D.

2. Operational Modes and Quality Control

Particle Mineral Analysis (PMA) mode of analysis is a two-dimensional mapping analysis where a pre-defined number of particles are mapped at a point spacing selected in order to spatially resolve and describe mineral textures and associations. The data is processed offline using the iDiscover software to calibrate the mineral database and to categorize the minerals.

The Specific Mineral Search (SMS) mode of analysis is a modified PMA routine. However, in an SMS routine, a phase reports as a low-grade constituent and can be located by setting a threshold limit of the back-scattered electron intensity (or mineral brightness depending upon the atomic weight of the elements present), with any particles above this value being mapped in two dimensions. Any accompanying phases of a lower brightness within the composite particle are also mapped. For example, this mode of measurement would be selected in ores of low sulphide grade, searching specifically for particles containing sulphide minerals.

Field Scan (FS) mode of measurement maps a core sample (or coarse size particulate sample) that has been mounted in the polished section. It collects a chemical spectrum at a set interval within the field of view. Each field of view is then processed offline and a pseudo image of the core sample is produced. For particulate samples, the data is further processed in order to produce individual particles for exposure and size calculations.

A comparison of the mode of analysis and the number of particles scanned for each sample is presented in Table 4. The modal mineralogy data is based on the analysis of over 9,000 particles per sample.

Table 4: Number of Particles Scanned

Sample ID	QEMSCAN Analysis Mode	No. of Particles Scanned
HC-1/COL-1	PMA	15,670
	SMS	2,044
HC-1/COL-1 DUP	PMA	13,431
	SMS	1,737
HC-2/COL-2	PMA	51,571
	SMS	1,904
HC-3/COL-3	PMA	37,793
	SMS	5,421
HC-4	FS	11,931
HC-5	FS	9,970
HC-6	FS	12,290

*SMS mode only maps sulphides and their associations

It should be noted that the energy dispersive X-ray characteristics for magnetite and hematite are nearly identical and these two minerals have a lower confidence level than the other minerals distinguished by QEMSCAN; light elements such as Li, B, C, Be, O and H also cannot be discriminated.

2.1. X-Ray Diffraction Analysis

Rietveld XRD analysis was performed on samples HC-1/COL-1, HC-4 and HC-6 for QEMSCAN calibration and quality control purposes. The XRD results are summarized in Table 5 and the complete XRD report with the patterns are presented in Appendix B. In general, the XRD results are consistent with the QEMSCAN analysis.

Table 5: Summary of XRD Analysis

Mineral/Compound	HC-1/COL-1 MAR4504-01 (wt %)	HC-4 MAR4504-02 (wt %)	HC-6 MAR4504-03 (wt %)
Quartz	1.8	27.0	1.7
Albite	25.3	24.2	25.3
Anorthite	7.6	4.6	5.0
Microcline	35.1	16.4	35.9
Magnetite	4.8	2.3	4.2

Grossular	0.5	0.3	0.5
Almandine	-	2.1	0.9
Fluorapatite	-	-	0.6
TOTAL	100	100	100

2.2. QEMSCAN Assay Reconciliation

The QEMSCAN mineralogical assays were regressed with the chemical assays (Figure 1) and are based on the PMA and FS data. The certificate of analysis is presented in Appendix A. The QEMSCAN calculated assays show good correlation with the chemical assays with the overall correlation as measured by the R-squared criteria of 0.99 and a slope (m) of 0.97.

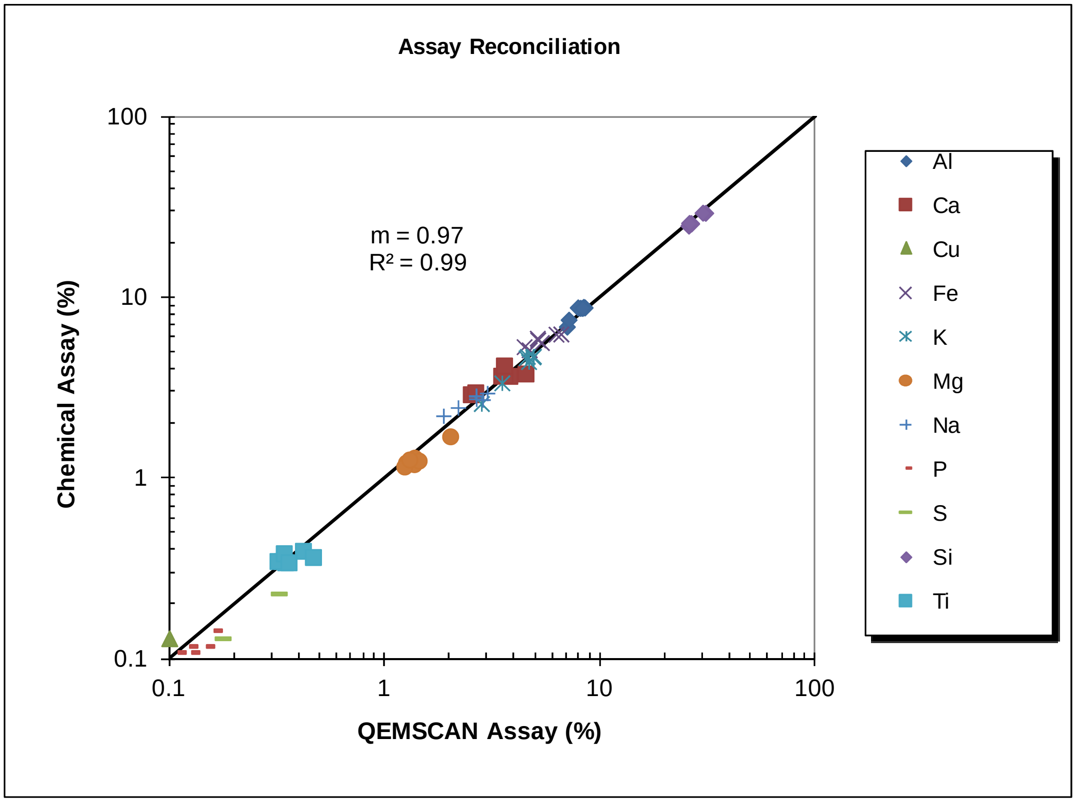

Figure 1: Quality Control – QEMSCAN Calculated vs. Direct Assay Reconciliation

2.3. Bulk Mineral Characterization

The modal abundances (wt%) of the minerals measured by QEMSCAN are presented in Table 6 and graphically illustrated in Figure 2.

The main sulphides present in the samples are pyrite, chalcopyrite and bornite ranging from 0.10% in HC-4 (0.08%, 0.02% and nil, respectively) to 0.64% in HC-6 (0.40%, 0.23% and 0.02%, respectively). The main carbonates are calcite and iron-rich dolomite ranging from 1.15% in HC-4 (0.72% and 0.43%, respectively) to 4.50% in HC-6 (4.45% and 0.05%, respectively). All of the samples are primarily comprised of potassium-feldspar (23.7% to 43.0%) and plagioclase (19.4% to 29.0%), with moderate amounts of quartz in HC-4 (27.1%) and HC-5 (21.3%).

Using the XRD results for samples HC-1/COL-1, HC-4 and HC-6 show that the Fe-oxides consist of magnetite (4.8%, 2.3% and 4.2%, respectively) and hematite (1.7%, 2.2% and 1.7%, respectively).

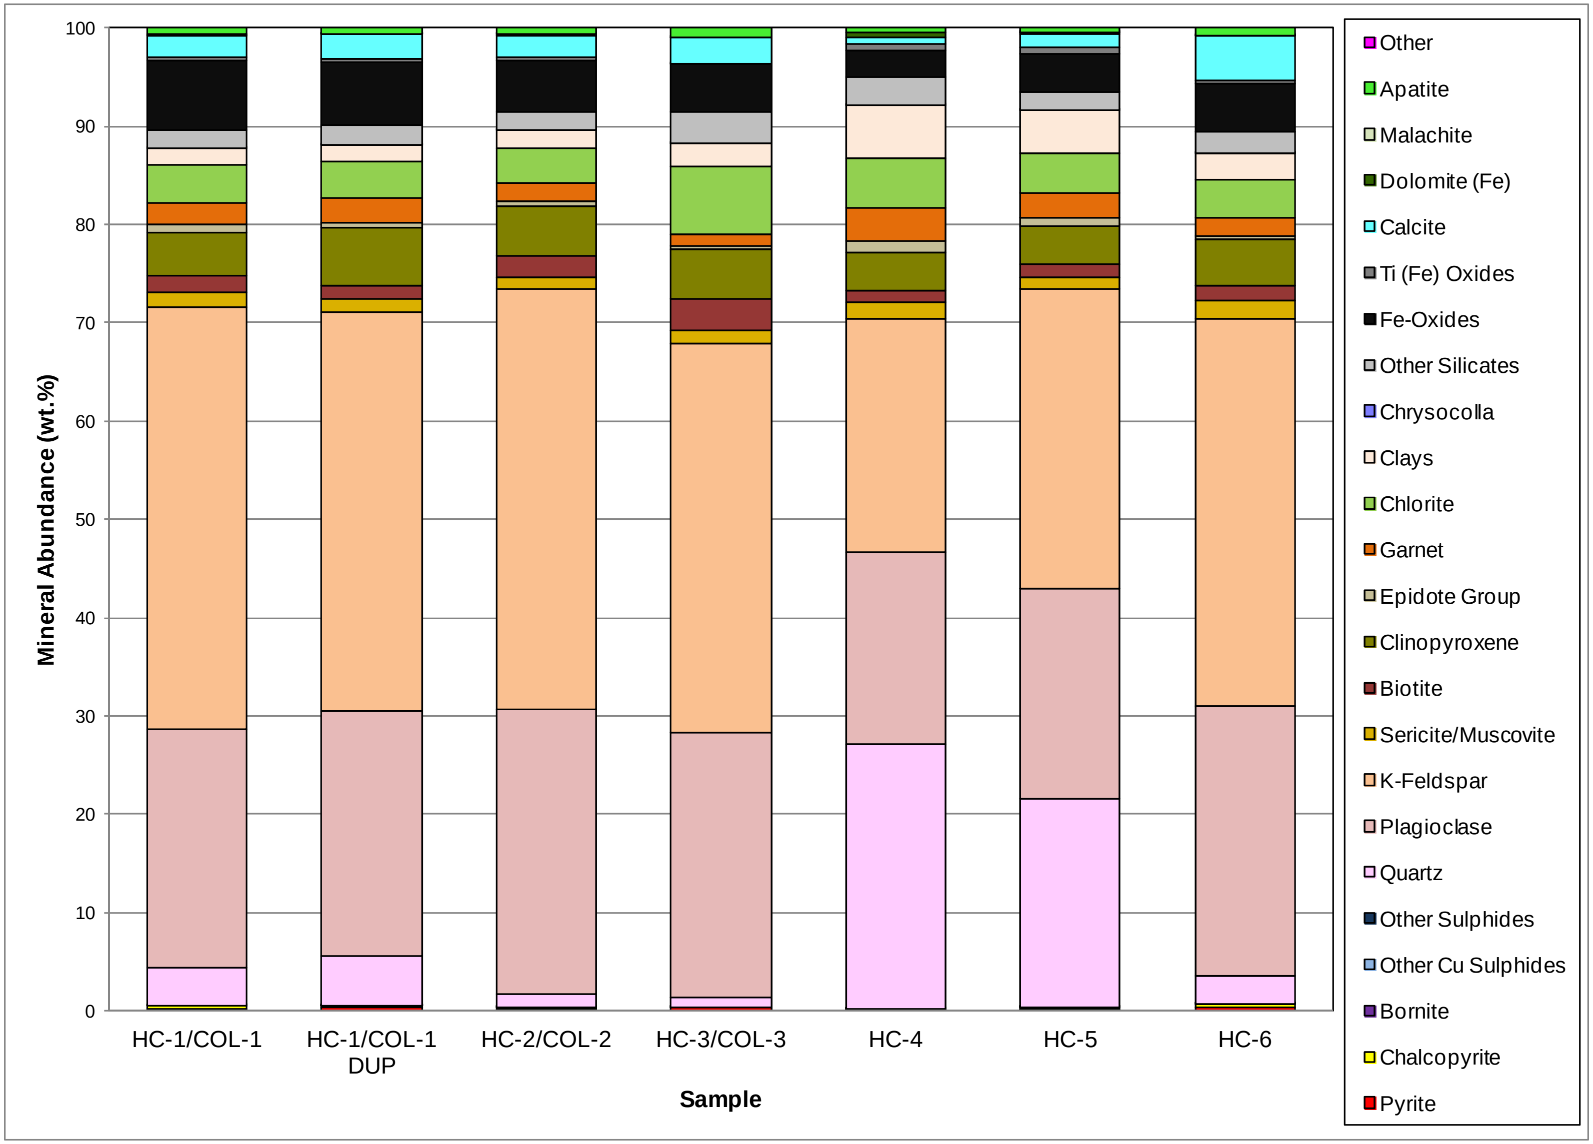

Figure 2: Modal Mineral Abundances by QEMSCAN

3. Elemental Deportment

Electron Microprobe Analysis was carried out on the main sulphides, silicates and carbonate minerals to determine their chemical compositions and to define the possible carriers of copper and selenium. The average elemental compositions (in weight percent) are summarized below and the complete EMPA report is presented in Appendix C.

The elemental distribution data are given in weight percent. The deportment calculations are based on the average elemental composition from the EMPA analysis and QEMSCAN modal distributions. The absolute data is presented in Appendix D.

3.1. Electron Microprobe Analysis

The average elemental compositions are below from Table 7 to Table 9. Copper (Cu) is carried in the silicate minerals by an Al-Fe silicate phase (which possibly resembles a chlorite texture) and chlorite with an average of 1.85% and 0.41%, respectively. The value of 1.85% copper within the Al-Fe silicate could fine grained copper oxide within the silicates which shows possible copper remobilisation. Images from the electron microprobe can be seen in Appendix C (Figure 2 within the appendix), which shows higher copper zoning around holes within the particle (this was also seen under the QEMSCAN SEM). Further work is needed in order to fully understand this copper occurrence within these altered particles.

All of the silicates have selenium (Se) below detection limits of the EMPA.

The average copper content in bornite and chalcopyrite is 62.2% and 34.3%, respectively. Pyrite contains an average of 0.02% copper, which is at the detection limit of the electron microprobe. Bornite carries 0.06% of the selenium which is based only on four particles analysed and thus the result must be interpreted with caution. Chalcopyrite and pyrite have selenium below the detection limits of the electron microprobe. It is recommended that Laser Ablation be carried out on the other sulphides as it has a lower detection limit than the electron microprobe to further understand the deportment of selenium.

The average concentration of iron (Fe) in dolomite is 6.44% and in calcite 0.13%. Dolomite is referred to as dolomite (Fe) within the report due to its iron content.

3.2. Selenium Deportment

Based on the EMPA data all of the selenium (Se) in the samples is carried by bornite. However, the presence of selenides as micrometric inclusions within the sulphides cannot be excluded which are impossible to identify with the QEMSCAN. Note that this is only based on four bornite particles, and must be taken into context of the overall grade of the selenium within the samples.

3.3. Copper Deportment

The elemental distribution of copper (Cu) in the seven samples is presented below in Figure 3. Pyrite was not included in the deportment data due to the amount (0.02%) being at the detection limit of the electron microprobe and only eight grains being analysed. The Al-Fe silicate that contains 1.85% copper has also not been included in the copper deportment because there were only four analyses taken.

In samples HC-1/COL-1, HC-1-COL-1 DUP, HC-2/COL-2, HC-5, and HC-6, copper is predominantly carried in the chalcopyrite (62-67%), followed by chlorite (14-22%), bornite (10-19%), and chalcocite/covellite (1-8%) accounting for the majority of the remainder.

In samples HC-3/COL-3 and HC-4, copper is predominantly carried by chlorite (78%), followed by chalcopyrite (17-20%) and chalcocite/covellite (1-3%).

From the QEMSCAN data an iron oxide/silicate was defined that contained copper (2% copper was used as a tentative value for the deportment analysis), but as this was not found during the probe work, so the exact chemistry is unknown at this time. Further work is recommended on defining this phase.

Note that the copper value (0.41%) assigned to chlorite. However, this value can vary widely, due to the copper present being very fine grained (micrometric) and/or present within the crystal structure which cannot be defined properly by the QEMSCAN. Thus, caution must be taken when using this data as there could be an overestimation of the amount of copper that is contributed by chlorite.

4. Mineral Characteristics

4.1. Mineral Exposure

Mineral exposure measures the surface exposure of the mineral or minerals of interest which could correlate with the ARD potential of a sample. For example, if the phases are well exposed the potential for reactivity is greater; but if the carbonate exposure is also high, then the ability of these particles to neutralize acid is more significant.

Exposure measures the surface exposure of the mineral or minerals of interest, with exposed minerals containing a surface exposure greater than 80%. Both the mineral exposure for the sulphide and carbonate minerals is presented below in weight percent and is based on the as received -2 mm fraction.

4.1.1. Sulphide Exposure

The sulphide exposure data are presented in Figure 4. Sulphides are defined as the combination all of the sulphides as one mineral group (pyrite, chalcopyrite, bornite etc.). An image grid and particle maps, which visually illustrates the sulphide exposure within the particles are presented

Figure 5Figure 5 and Figure 6, respectively. The absolute data are presented in Appendix D.

Sample HC-3/COL-3 shows the highest exposure with 47.0% exposed (>80% exposed), and 19.3% between 20-80% exposed. The remainder is less than 20% exposed (26.5%) and locked (7.2%). HC-6 shows the lowest exposure with 81.8% less than 20% exposed, 9.1% exposed, and 3.1% between 20-80% exposed. The remainder (5.9%) is locked. HC-4 has the highest percentage of locked sulphides at 25.3%.

	HC-1/COL-1	HC-1/COL-1 DUP	HC-2/COL-2	HC-3/COL-3	HC-4	HC-5	HC-6

4.1.2. Carbonate Exposure

The carbonate exposure data are presented in Figure 7. The carbonates group is defined as a combination of calcite and dolomite. An image grid and particle maps, which visually illustrates the carbonate exposure within the particles are presented in Figure 8 and Figure 9, respectively. The absolute data are presented in Appendix D.

Sample HC-3/COL-3 shows the highest exposure with 78.9% exposed (>80% exposed) and 14.3% between 20-80% exposed. The remainder is less than 20% exposed (6.4%) and locked (<1%). HC-6 shows the lowest exposure with 27.9% exposed, 34.0% between 20-80% exposed, 37.1% less than 20% exposed and (<1%) locked.

4.2. Particle Size

Particle size is calculated for the sulphide and carbonate minerals.

4.2.1. Sulphide Size

The data of the sulphide size is presented in Figure 10. The absolute data is presented in Appendix D.

Sample HC-3/COL-3 contains the finest sulphides with 88.4% of the mass at less than 30 µm, and the remainder (11.6%) between 30-40 µm; whereas sample HC-4 contains the coarsest sulphides with 17.6% greater than 75 µm, 21.7% between 30-75 µm and 60.7% less than 30 µm in size.

	HC-1/COL-1	HC-1/COL-1 DUP	HC-2/COL-2	HC-3/COL-3	HC-4	HC-5	HC-6
<5 µm	0.00	0.00	0.00	3.92	0.00	0.00	0.00
5-10 µm	5.41	3.78	6.69	23.8	0.00	0.00	0.00
10-20 µm	26.3	24.6	26.3	43.4	46.2	21.6	17.2
20-30 µm	23.7	13.4	32.3	17.3	14.5	16.8	20.7

>100 µm	0.00	6.46	0.00	0.00	17.6	0.00	6.02

Figure 10: Sulphide Particle Size (Normalized)

4.2.2. Carbonate Size

The carbonate minerals size data is presented in Figure 11. The absolute data is presented in Appendix E.

Sample HC-3/COL-3 contains the finest carbonates with 65.3% of the mass at less than 30 µm in size, and 34.7% between 30-75 µm; whereas sample HC-6 contains the coarsest carbonates with 59.3% greater than 100 µm, 32.3% between 30-75 µm, and 8.4% at less than 30 µm in size.

	HC-1/COL-1	HC-1/COL-1 DUP	HC-2/COL-2	HC-3/COL-3	HC-4	HC-5	HC-6
<5 µm	0.00	0.00	0.00	4.25	0.00	0.00	0.00
5-10 µm	1.19	1.18	2.46	16.5	0.00	0.00	0.00
10-20 µm	7.59	6.99	9.08	27.9	3.09	4.68	1.36
20-30 µm	14.8	14.5	13.8	16.5	7.93	8.20	7.06
30-40 µm	12.8	10.9	14.4	4.00	6.24	15.3	9.35
40-50 µm	11.1	11.4	8.27	7.30	8.03	7.29	9.05
50-75 µm	13.5	18.0	19.7	23.4	6.29	10.5	11.9
75-100 µm	4.42	6.98	12.0	0.00	4.64	7.44	1.95
>100 µm	34.6	30.1	20.2	0.00	63.8	46.5	59.3

Figure 11: Carbonate Particle Size (Normalized)

Conclusions and Recommendations

- The main sulphides present are pyrite, chalcopyrite and bornite.
- Carbonates have been identified as calcite and iron bearing dolomite (from EMPA data).
- Iron-oxides consist of magnetite and hematite, as identified by Rietveld XRD.
- The main carriers of copper have been identified as chalcopyrite, bornite, chalcocite/covellite, enargite and silicates such as chlorite and an iron oxide/silicate phase.
- Selenium was identified in four bornite grains that were above the detection limit of the EMPA. However, the presence of selenides as micrometric inclusions within the sulphides cannot be excluded which are impossible to identify with the QEMSCAN. It is recommended that additional work like SEM and Laser Ablation be carried out to further investigate this, which is beyond the scope of this project.
- HC-3/COL-3 contains the highest exposed sulphides (>20% exposure) at 66% and HC-6 the lowest at 12%.
- HC-3/COL-3 contains the highest exposed carbonates (>20% exposure) at 93% and HC-6 the lowest at 62%.
- The majority of the sulphides are <75 µm in size.
- The carbonates range in size with HC-3/COL-3 containing the finest carbonates at 65.3% of the mass less than 30 µm in size and sample HC-6 with the coarsest carbonates at 59.3% greater than 100 µm.

1 INTRODUCTION

On behalf of Mount Polley Mining Company (MPMC), the Environment & Water business unit of SNC-Lavalin Inc. (SNC-Lavalin) has completed this Soil Quality Impact Assessment (SQIA) for the Hazeltine Creek study area (study area) near the Mount Polley Mine (Mine) near Likely, British Columbia (BC). The SQIA was completed as part of an assessment of impacts associated with the tailings dam failure of August 4, 2014.

1.1 Scope and Objectives

The work described herein was conducted in general accordance with Chapter IV of the SNC-Lavalin proposal submitted to MPMC titled *Mount Polley Comprehensive Environmental Impact Assessment Work Plan* dated August 29, 2014 (SNC-Lavalin 2014). The primary objective of the SQIA was to characterize tailings and native soils in the receiving environment to assess potential impacts associated with the tailings release event. The SQIA provides data for understanding the human health and environmental health risks associated with the impacts, including information to identify potential plant growth limiting soil conditions for consideration during immediate and long term reclamation efforts. The assessment included efforts to support estimating the physical distribution of tailings from below the Tailings Storage Facility (TSF) to the shore of Quesnel Lake through both lateral and vertical delineation sampling and use of aerial photograph imagery. Limitations, including with respect to delineation, are summarized in Section 1.4 with details provided as appropriate throughout the document. SNC-Lavalin worked cooperatively with SRK Consulting (Canada) Inc. (SRK) in the execution of the field sampling. As a result of shared sampling methods and soil samples, the data for the SQIA and the geochemical characterization work undertaken by SRK are complementary.

For the purposes of the SQIA, "soil" refers collectively to the various material classes that were sampled and includes native *in situ* soils, tailings, and/or mixtures of tailings and native soil and/or sediments translocated as a result of the TSF breach, except where specified. The term "tailings" refers to material representative of tailings alone, and more often a mixture of tailings and translocated native soils and/or sediments. Subaqueous sediments (including tailings) within Quesnel Lake, Polley Lake, and from the Hazeltine Creek channel were sampled as part of the Sediment Quality Impact Characterization, results of which are provided in the associated report (Minnow 2015).

Findings related to sediment and tailings geochemistry, including with respect to leachability, are provided in the Sediment Quality Impact Characterization report (Minnow 2015), and the Geochemical Characterization of Spilled Tailings report (SRK 2015). Findings related to hydrotechnical and geomorphological impacts are provided in SNC-Lavalin's Hydrotechnical and Geomorphological Impact Assessment (HIA) Report (SNC-Lavalin 2015).

1.2 Study Area

The SQIA characterized soils within the Hazeltine Creek study area, defined as the area affected by the TSF breach, within the Hazeltine Creek channel that extends from the former dam wall and Polley Lake (Upper Hazeltine Creek) through to its confluence with Quesnel Lake. The study area is approximately 9 kilometres (km) long and up to 1 km at its widest point (in the area of Lower Hazeltine Creek near Quesnel Lake). The study area, as defined in this SQIA, is further divided into nine smaller Study Areas based on position along the Hazeltine Creek Channel. References to these specific Study Areas are consistent with those defined in the Post-Event Environmental Impact Assessment Summary Report (PEEIAR) authored by Golder Associates Ltd. (Golder) on behalf of MPMC (refer to Figure 1, Golder 2015).

An area referred to as the Hazeltine Canyon is located approximately two-thirds of the distance between the TSF and Quesnel Lake. This area presented unique access and safety considerations due to the presence of steep and potentially unstable slopes and specific limitations with respect to sampling in this area are provided in Section 1.4 and Section 3.2.1. A detailed description of the physical setting of the study area, including with respect to pre-disturbance conditions, are provided in the HIA (SNC-Lavalin 2015b).

1.3 Report Structure

This SQIA report is a technical appendix to the PEEIAR (Golder 2015). The reader should refer to the Glossary of Terms within the PEEIAR for definitions and abbreviations.

The following outlines the structure of this report:

- Introduction
- Background Review
- Soil Quality Assessment Methodology
- Impact Assessment Methodology
- Assessment Results
- Discussion
- Conclusion

1.4 Limitations

The study was limited by access constraints and geotechnical safety (instability) issues. These limitations influenced access to soil sampling transects, sampling equipment selection, and sampling locations within specific transects. Details on the sampling limitations are provided in Section 3.2.1. Based on a preliminary review of environmental soil quality data (i.e., total metals), batch leachability testing of native and background soils was not carried out as proposed in the SQIA Workplan (SNC-Lavalin 2014).

2 BACKGROUND REVIEW

SNC-Lavalin reviewed background information (aerial photographs) on the physical distribution of tailings following the TSF breach, reclamation reports for the Mine including with respect to pre-disturbance soil conditions, historical soil, landform and reclamation reports, and existing tailings inventory chemistry and mine processing reagent records. The background review was carried out to inform the design of the field program with respect to sampling locations and selection of soil analytical parameters for study.

2.1 Aerial Photographs and Topographic Survey Data

SNC-Lavalin estimated the physical extents of the tailings in the Hazeltine channel using the 20 centimetre (cm) resolution orthophotos and light detection and ranging (LiDAR) topographic survey data provided by MPMC that was collected by airplane on August 5, 2014. The aerial survey extent included the TSF, south end of Polley Lake, Hazeltine Creek and a portion of Quesnel Lake. SNC-Lavalin used the orthophotos and topographic survey data to develop base drawings for use during the field program and to assist in field sampling design. Roads and trails were added to the drawings, to assist in field navigation.

Using base drawings, SNC-Lavalin measured the Hazeltine Creek channel from Quesnel Lake to the TSF and established 18 soil sampling transects (approximately 1 transect per 500 metre [m] reach) along the Hazeltine Creek channel which would serve as the basis for the soil quality assessment. Details on the soil sampling methodology are provided in Section 3.2. In total, 11 base drawings were developed for the field investigation. These drawings were later updated with sample locations (Drawings 621717-4-3-P1 to 621717-4-3-P11, attached).

2.2 Surficial Geology and Soil Survey Information

As part of the SQIA, historical soil and surficial geology survey information was reviewed (Imperial Metals 1990; Lord 1984; Bicheler and Bobrowsky 2003). As outlined by these historical reports, large parts of the Canadian Cordillera were covered by interconnecting valley and piedmont glaciers at several different times during the Pleistocene. This glacial mass is known as the Cordilleran Ice Sheet. Most of the Interior Plateau features prominent land forms that are the results of glacial and glaciofluvial processes. Morainal tills are the most extensive sediments in the vicinity of the Mine. These are sediments laid down by glacial ice with little or no re-working by melt-water. As a result, these tills tend to be massive or crudely stratified and poorly sorted with a wide range of particle sizes.

Table A summarizes surficial geology as identified by Bicheler and Bobrowsky (2003) in the study area. A detailed interpretation of surficial geological information is provided in the Hydrotechnical and Geomorphological Impact Assessment Report (SNC-Lavalin 2015b).

Table A: Summary of Surficial Geology in the Hazeltine Creek Study Area

Area	Type	Quarternary Geology	Surface Expression
Upper Hazeltine Creek	Pleistocene Morainal / Glaciofluvial	• Pleistocene Morainal described as poorly sorted, moderate to well compacted, clayey to silty diamicton. Clasts are subrounded to subangular, range from pebbles to boulders and may be faceted and/or striated. Interpreted as lodgement till. Irregular sand and gravel lenses may be present where till was deposited subaqueously or in association with flowing water.	Rolling; blanket
		• Morainal was more extensive than Glaciofluvial. Glaciofluvial was described as typically moderately sorted, weak to moderately compacted, cobble or boulder cobble gravel with a sand matrix. Clasts are rounded to subrounded. They are found as well-defined terraces in the major valleys up to approximately 70 m above river level or as irregular deposits at higher elevations on valley slopes or on plateaus. They are associated with melt-water channels or drainage courses.	Blanket
Lower Hazeltine Creek	Pleistocene Morainal / Glaciofluvial	• Occurrences are similar to Upper Hazeltine Creek, however Pleistocene Morainal was indicated to be more extensive than Glaciofluvial deposits, and found overtop of hummocky bedrock.	Blanket; hummocky

Soils are formed from the parent materials interacting over time with topography, climate and biota. Soil mapping was undertaken by the British Columbia Soil Survey in 1984 and shows that the area impacted by the tailings release was covered by Mesisol, Luvisol and Brunisol soil orders, which are noted as being derived from morainal tills, glaciolacustrine sediments and colluvium. Organic soils (Meisols) and Gelsols with poor drainage characteristics were described for areas at both ends of Polley Lake. Drawing 621717-4-1 (attached) and Table B provide an overview of the soil types found within the study area (Lord 1984).

Table B: Summary of Soils in the Hazeltine Creek Study Area

Area	Soil Type	Material	Surface Expression	Water Regime of Dominant Soil	Classification of Dominate Soil
Polley Plug; Upper Hazeltine Creek	Catfish Creek – Spakwaniko (CC-SW/2)	Moderately decomposed sedge fen peat and loamy morainal and colluvial materials	Level, undulating	Aquic, very poorly drained, moderately pervious	Typical Mesisol
Upper Hazeltine Creek	Lanezi – Deserters (LZ-D/3-4)	Loamy morainal, and sandy and loamy morainal and colluvial materials	Inclined, ridged, blanket and veneer	Perhumid to humid, moderately well drained, moderately pervious	Luvisolic-Humo-Ferric Podzol
Lower Hazeltine Creek	Moffat Lakes – Lanezi (MF-LZ)	Gravelly, sandy and loamy skeletal and loamy morainal materials	Undulating, rolling	Humid to subhumid, well drained, moderately to rapidly pervious	Eluviated Dystric Brunisol

2.3 Stage I Environmental and Socioeconomic Impact Assessment Report

Information from baseline environmental and socioeconomic impact studies conducted for the Mount Polley Project in 1989 and 1990 as part of Mine permitting (Imperial Metals 1990) was reviewed. This section summarizes the relevant information SNC-Lavalin obtained from the review with respect to baseline information on the metallurgical process and mine processing reagents, tailings characteristics, surficial geology and soils survey information, and on the conceptual reclamation plan.

At the Mine, the report described the copper-gold ore process to crush, grind and subject materials to a flotation circuit to concentrate target minerals, before discharging tailings to the TSF. Information on the mine processing reagents is provided in Section 2.4. Within the Stage I Environmental and Socioeconomic Impact Assessment Report (Imperial Metals 1990), tailings material was described as a non-plastic, yellow-grey, fine grained material with 6% clay, 64% silt and 30% fine sand. The report described acid base account testing which determined that the tailings were a net acid consumer. It also concluded that leachate testing determined that tailings would not be considered special waste under the BC Waste Management Branch regulations (now the *Hazardous Waste Regulation* [BC Ministry of Environment, 2009a]*)* and humidity cell testing demonstrated that the tailings exhibited low reactivity. SNC-Lavalin used this information as a basis for anticipating soil and total metals concentrations and establishing contaminants of potential concern (COPC). Historical tailings inventory and pre-release chemistry data is further discussed in Section 2.4.

Imperial Metals assessed surficial geology and soil as part of determining impacts to terrestrial resources. Surficial Geology and Soil is further discussed in Section 2.2. The stated reclamation objective in the conceptual reclamation plan was to return lands affected by the Mine to their original use and capability to the extent practical. Imperial Metals proposed a phased reclamation strategy for exploration and construction, mine operation and mine closure and decommissioning project phases which would incorporate results of an ongoing reclamation research and planning program. The reclamation research and planning program resulted in a number of reports that are summarized in Section 2.6.

2.4 Mine Processing Reagent Records

Mine processing reagents are introduced in the extraction process, primarily to extract target metals and to clarify process water. SNC-Lavalin completed a review of MPMC mine processing reagent records provided by MPMC that were known to have been used at the mill between 2009 and 2014 (MPMC 2014). SNC-Lavalin carried out an examination of MPMC-provided Material Safety Data Sheet (MSDS) and supplier-provided chemical information related to the mine processing reagents to identify key chemical constituents. A preliminary review of readily available toxicological information was carried out for chemical constituents considered indicator parameters and discussions were had with several Canadian commercial environmental laboratories to confirm the feasibility of laboratory analysis. Table C provides a summary of mine processing reagents MPMC used at Mount Polley between 2009 and 2014 (MPMC 2014).

Table C: Summary of Mine Processing Reagents used at Mount Polley 2009 to 2014

Process Reagent (in kilograms)	2009	2010	2011	2012	2013	2014
Potassium amyl xanthate	120,045	116,450	140,250	98,750	91,800	45,900
Methyl isobutyl carbinol (MIBC) Frother	136,493	-	-	-	-	-
Sodium hydrosulphide	186,093	246,927	82,962	6,239	1,133	-
Flocculant	474	673	479	672	1,053	498

Table C (Cont'd): Summary of Mine Processing Reagents used at Mount Polley 2009 to 2014

Process Reagent (in kilograms)	2009	2010	2011	2012	2013	2014
Aero 208 / Danaflot 468	19,115	3,944	-	-	-	-
R200M	2,250	-	-	-	-	-
Lime (Calcium Hydroxide)	2,564,726	2,870,676	2,120,114	1,394,798	1,403,483	351,680
Nalco	4,692	-	-	-	-	-
W22 Frother	27,851	93,323	86,076	104,852	139,424	55,475
TNC 312 / R200M	-	2,000	-	-	-	-
Eliminice	-	7,872	-	-	-	-
IPAC 6832 (dust/de-icer)	-	-	85,434	22,086	49,753	-
3180M	-	-	9,553	6,804	908	-
A208 / A7048	-	-	1,786	-	-	-
Promoters (O68)	-	-	-	225	515	-

Although the addition of diesel and oils to the flotation circuit was confirmed to not be current practice at the Mine, extractable petroleum hydrocarbons (EPH) were included as COPC as diesel and oils are constituents of W22C Frother. Similarly, methyl isobutyl ketone (MIBK) was included as a COPC in relation to historical practices at mine that pre-date 2009, and may be associated with degradation products of methyl isobutyl carbinol (MIBC) or may be present in residual quantities due to its potential use in the manufacturing of MIBC.

Specific indicator parameters for inorganic agents quicklime, IPAC 6832 (de-icer) and sodium hydrosulfide do not exist, and thus a review of effects upon inorganic parameters (pH, salinity / sodium, alkalinity, etc.) was undertaken to identify any general effects that may be attributable to these agents in the receiving environment. Chemicals such as phosphorodithioic acid (associated with the Aerofloat 208) and polyoxyalkylene alkyl ether (associated with W22C Frother) could not be analyzed by the Canadian commercial environmental laboratories that were contacted by SNC-Lavalin (AGAT Laboratories based in Mississauga, Ontario and ALS Environmental of Vancouver, BC). Chemical product information and/or MSDS information for 3190M, TNC312/R200M, Nalco and Eliminice was not available for review.

Based on the review of mine processing reagents, the following inorganic parameters were considered potential indicators and were included in the analytical program of the SQIA:

- Total xanthates: indicator for presence of potassium amyl xanthate.
- Carbon disulphide: a trace constituent and possible degradation byproduct in relation to potassium amyl xanthate.
- Total glycols: indicator for Promoter O68.
- MIBC and MIBK: indicators for W22C Frother and MIBC Frother.

2.5 Tailings Composition Records

The chemical composition of the Mine tailings in the TSF was characterized by MPMC as part of mine operations support and ongoing geochemical characterization studies. Tailings chemistry reflects the mineralogy and composition of the mined ore, which is primarily potassium feldspar and albite-altered breccias (Imperial Metals 1990). Trace minerals that are recovered as ore also include chalcopyrite with minor amounts of bornite, covellite, chalcocite, magnetite and digenite. MPMC has provided tailings inventory data in Annual Environmental and Reclamation Reports submitted to the Ministry of Energy and Mines (MEM) and Ministry of Environment (MoE). Table D provides a summary of the total metals concentrations (MPMC 2014) from pre-release chemistry data provided by MPMC in August 2014 (MPMC 2014). As such, the primary COPC associated with the tailings are metals, which may be present in elevated concentrations relative to natural conditions in the area.

Table D: Summary of Average Tailings Composition Between 2010 to 2014

Element	Average Total Concentration of Tailings Solids (mg/kg)
Aluminum (Al)	19,139
Antimony (Sb)	0.43
Arsenic (As)	12.32
Barium (Ba)	222
Beryllium (Be)	0.63
Bismuth (Bi)	1.85
Cadmium (Cd)	0.16
Calcium (Ca)	28,122
Chromium (Cr)	20.3
Cobalt (Co)	17.4

Table D (Cont'd): Summary of Average Tailings Composition Between 2010 to 2014

Element	Average Total Concentration of Tailings Solids (mg/kg)
Copper (Cu)	931
Iron (Fe)	49,651
Lead (Pb)	5.35
Lithium (Li)	17
Magnesium (Mg)	10,969
Manganese (Mn)	652
Mercury (Hg)	0.49
Molybdenum (Mo)	5.37
Nickel (Ni)	104.61
Phosphorus (P)	1405
Potassium (K)	2121
Selenium (Se)	1.04
Silver (Ag)	116.01
Sodium (Na)	1,438
Strontium (Sr)	192.12
Thallium (Tl)	0.025
Tin (Sn)	1.5
Titanium (Ti)	1525
Uranium (U)	15.61
Vanadium (V)	180.54
Zinc (Zn)	59.44

2.6 Historical Soils, Landforms and Reclamation Reports

As part of the background review, SNC-Lavalin reviewed historical soil, landform and reclamation reports in order to identify pre-release chemistry and soil physical properties relevant to contaminant chemistry (e.g., texture, particle size, consistency, colour, etc.) for soil in the study area. Reports reviewed as part of the SQIA are referenced in Section 9, and relevant information is summarized below.

In 1995, a pre-development soil survey was completed to assess native soil quality prior to mine site construction (Hallam Knight Piésold Ltd. 1995a) which assessed texture, particle size, rooting depth/size, consistency, colour, available nutrients and soil metals concentrations at the mine and mill areas, and the TSF. As part of the study, summary descriptions for 29 test pit locations were provided along with the analysis of 32 mineral soil samples collected from shallow mineral soil. Analytical results are presented in Table E for the mine and mill areas, and the TSF.

Table E: Summary of Pre-Disturbance Mineral Soil Quality

Parameter	Proposed Mine and Mill Areas (n=18)			Proposed TSF Area (n=14)		
	Minimum	Maximum	Average	Minimum	Maximum	Average
pH	4.9	6.2	5.4	5.0	6.6	6.0
Copper (mg/kg)	86	1980	521	17	59	31
Vanadium (mg/kg)	65	165	120	29	91	66
Organic Matter (%)	0.33	11.2	3.57	0.24	3.70	1.05
Total Nitrogen (mg/kg)	0.02	0.34	0.11	0.02	1.50	0.15

As part of the soil survey completed in 1995, soils and landforms and agricultural capability of the mill, mine and TSF were assessed (Hallam Knight Piésold Ltd. 1995b). Soils in the area of the TSF were found to be developed on morainal deposits, underlain occasionally by lacustrine parent materials, with depth to bedrock measured up to 20 m below ground surface (bgs) (Hallam Knight Piésold Ltd. 1995b).

Following development of the Mine, a number of soil inventories and reclamation research reports were completed (Forestmeister Services 2006, 2007a, 2007b, 2014a, 2014b; Inland Timber Management Ltd. 2004) to support final reclamation at the Mine. Reclamation research included establishing vegetation and tree survey plots with various amendment combinations of overburden, fertilizer, biosolids, tailings and waste rock and then assessing metals content in vegetation tissue (Forestmeister Services 2007a). Reclamation research is reportedly ongoing to monitor tree growth overtime in soil with tailings and biosolids amendments (Forestmeister Services 2014b). During the review of reclamation research reports, SNC-Lavalin did not identify total copper and vanadium concentrations for tailings amended into vegetation and tree survey plot soils.

2.7 Summary of COPC

Based on the background review, the following COPC were identified and assessed as part of the SQIA. A list of COPC and their associated regulated analytical parameters are presented in Table F.

Table F: Summary of COPC and Analytical Parameters in Tailings and Mine Processing Reagents

Source	COPC	Soil Analytical Parameters
Tailings	Metals, pH	Total metals, pH
Mine Processing Reagents	Xanthates, VOCs (including carbon disulphide, 2-hexanone, MIBC, MIBK), glycols, LEPH, HEPH, PAHs	Xanthates, VOCs (including carbon disulphide, 2-hexanone, MIBC, MIBK), glycols, LEPH, HEPH, PAHs

HEPH – heavy extractable petroleum hydrocarbon
LEPH – light extractable petroleum hydrocarbon
MIBC – methyl isobutyl carbinol
MIBK – methyl isobutyl ketone
PAH – polycyclic aromatic hydrocarbons
VOCs – Volatile Organic Compounds

3 SOIL QUALITY ASSESSMENT METHODOLOGY

The following sections present the methodology for the SQIA. The sampling personnel followed SNC-Lavalin's preferred operating procedures (POPs) which are consistent with MoE requirements and industry standards. The SQIA methodology included a review of background information, completion of preliminary field observations and a soil investigation.

Select photographs taken during the field investigation, organized by site setting and sampling (Photographs 1 to 18) and background sample locations (Photographs 19 to 36) have been provided in Appendix I. Analytical laboratory methods used by ALS Environmental of Vancouver, BC (ALS) and affiliate laboratories are summarized in Appendix II. Quality Assurance/ Quality Control (QA/QC) methods are described in Section 3.6 and Appendix III.

3.1 Preliminary Field Observations

SNC-Lavalin and SRK completed preliminary field observations in order to develop the sampling methodology for the SQIA. SNC-Lavalin was able to complete initial field observations while assessing site access and completing background soil sampling between September 2 and September 7, 2014. On September 8 and 9, 2014, SNC-Lavalin and SRK visited the various areas of the study area to observe the distribution of tailings and their depositional environments along Hazeltine Creek to refine the sampling design. Tailings were observed to be deposited within the scoured channel of Hazeltine Creek (Photograph 2) and within the forest adjacent to Hazeltine Creek (Photograph 6 and 9). Within the affected area, tailings were observed in what appeared to be different depositional environments based on surface characteristics including texture, colour, and/or apparent moisture content and degree of saturation. These apparent depositional environments were mapped, in part using aerial photographs in the field. These observations formed the basis for developing the approach for their sampling and characterization (refer to Section 3.2.1).

Two primary tailings types were identified based on visually apparent properties such as colour, texture, and field observable geochemical properties (i.e., magnetism, field carbonate effervescence class, and visible mineralogy). Various parent materials were observed below a layer of tailings of variable thickness. Tailings appeared to be mixed with native soils to varying degrees.

Bedrock was observed within the Hazeltine Canyon above the Horsefly-Likely Forest Service Road (FSR), also locally referred to locally as the Ditch Road (Photograph 5). In places within the Hazeltine Canyon, the bedrock was exposed at surface and visible along channel sidewalls (Photograph 8). A clear boundary was apparent at soil transects as evidenced by the presence of tailings and high water marks on soil and/or vegetation. Soils beyond this boundary appeared unaffected by the TSF breach and these observations supported selection of background sampling locations approximately 10 m beyond the boundary.

As a result of these observations three material classes were identified and targeted in the sampling program: tailings, native within channel soil, and background soils. Details on the sampling methodology are provided in Section 3.2.

3.2 Soil Investigation

Field soil sampling activities related to the SQIA were carried out between September 3, 2014 and October 29, 2014 and were led by SNC-Lavalin personnel. Soil sampling activities between September 8 and September 16, 2014 were carried out in conjunction with SRK personnel.

During the soil investigation, soil samples were collected from three material classes, and these are referred to throughout the report. These material classes include tailings, native within channel soils, and background soils. Tailings samples were collected from material inferred to be representative of tailings alone, or mixed with other soils and/or sediments translocated as a result of the TSF breach. Native within channel soil samples were collected from within the boundaries of the tailings affected area. Lastly, samples considered representative of background conditions were collected at locations approximately 10 m outside the area affected by the tailings release with the exception of locations that were shifted due to the presence of native soil disturbance from existing or historical roads or trails. The extent of tailings deposition was based on visual observations. The methods relating to the assessment of soil physical properties are described in Section 3.3.

3.2.1 General Soil Sampling Methodology and Field Limitations

The soil sampling design involved establishing transects approximately every 500 m along the affected areas of Hazeltine Creek. Factors such as access and inferred soil variability, observed from high resolution aerial photo imagery were taken into account. A total of 18 transects were established as shown on Drawing 621717-4-2 (attached).

In order to obtain soil samples representative of the various apparent depositional environments across each transect, SNC-Lavalin developed transect specific sampling maps using high resolution aerial photographs to map the dominant soil units. Within each transect, units representing various depositional environments were established based on aerial photographs and field observations (e.g., suspect tailings depths, grain size, apparent moisture, etc.), and their width estimated. The field personnel then selected up to five dominant soil units across each transect to target for sampling. In the areas of Lower Hazeltine Creek and Upper Hazeltine Creek near the Polley Plug, five locations were established across the affected areas to account for higher observed variability in depositional environments. Additional tailings samples were occasionally collected, based on observed field variability within soil transects. In order to remove possible bias in selecting sampling locations within a unit, the horizontal position within each unit was selected at random.

Within each transect, one or more test pit sample locations were selected for stratigraphic observation or sampling from multiple depths to understand the vertical variability within the tailings and to characterize underlying native *in situ* soils. The selected test pit locations typically were those that exhibited increased apparent variability in material type. Native within channel soil samples were also occasionally collected from channel sidewalls along the scour path. This method was used opportunistically and did not require the excavation of test pits.

Various access and safety concerns were identified during the site visits. Steep ground and potentially unstable channel sidewalls (Photograph 4) forced the shifting of entire transects to accommodate access or to maintain safe working conditions. In addition, during the course of sampling individual transects, the above mentioned conditions as well as soft and saturated ground conditions occasionally required sampling locations to be adjusted. Specifically, loose unconsolidated wet tailings, unstable ground, unsafe channel sidewalls and changing water levels caused by changes to pump operations at Polley Lake affected where and how samples could be collected for the study. When deemed necessary, sample locations were field adjusted by selecting a new random horizontal position until a safe sampling location could be established. In some cases, the horizontal transect azimuth was adjusted slightly to avoid areas of safety concern.

At tailings sample locations, test pits were advanced using hand tools (i.e., spade shovel, post-hole shovel, soil auger) until native soils were encountered. At locations where tailings deposits were thick enough that their depth could not be ascertained, the underlying soil resources were not assessed. Probing with a spade shovel handle was done until refusal, and the shovel probe depths were recorded as an estimate of tailings depth. Native within channel soils were uncovered undisturbed soils along channel side walls or in native soil below tailings. Photographs were collected before and after sampling and field notes were taken to document relevant observations. Locations were recorded using both a Trimble GeoExplorer 6000 Geo-XH global positioning system (GPS) unit and on field sketches. SNC-Lavalin then used the Trimble GPS Pathfinder Office software program to correct GPS locations relative to a known GPS base station and this increased the accuracy of coordinates to between 0.5 m to 1.5 m. Sample locations were also verified by field personnel on drawings as part of QA/QC measures. Additional detail on QA/QC measures is provided in Appendix III.

Samples were collected of tailings and native within channel material types using a clean (de-contaminated) hand trowel, placed into two labelled 500 millilitre (mL) lab supplied glass jars and into one or more labelled clean Ziploc® or Poly-Ore bags (Photograph 16). To minimize the potential for cross-contamination, sampling tools were cleaned using de-ionized water and paper towel between each sample location.

Sample descriptions were logged in the field, including particle size, colour using the Unified Soil Classification System (USCS) (American Society for Testing and Materials [ASTM] D2487-11) and any evidence of contamination (i.e., suspected tailings, etc.) was recorded. The jars and bags were labeled and stored in ice-filled coolers and submitted to ALS for analysis under chain-of-custody documentation. A detailed summary of the analytical methods used by ALS and the associated references is provided in Appendix II.

Soil quality was not assessed beneath tailings between the Polley Plug and the TSF in upper Hazeltine Creek, due to the thickness of soft, saturated tailings sampling conditions and safety considerations noted above. Additional assessment would be necessary to characterize underlying native soils in this area. At the time of writing, results had become available for soils at two sample locations in the Polley Lake Plug area through sampling efforts carried out by MPMC staff; however, they have not been included in the scope of the SQIA. Further sampling of this area will be conducted as part of the planned ecological and human health risk assessment program (Golder 2015), and the recent MPMC results will be included in the associated reports.

3.2.2 Soil Contaminant Chemistry

To assess soil contaminant chemistry, SNC-Lavalin collected 71 tailings samples and 14 within channel native samples from 68 separate locations. Samples were submitted samples to ALS for analysis of total metals, pH, moisture, light and heavy extractable petroleum hydrocarbons (LEPH/HEPH), PAH, glycols, volatile organic compounds (VOC) (including carbon disulphide, 2-hexanone, MIBC, MIBK) and xanthates. SNC-Lavalin placed soil samples directly into clean laboratory provided 500 mL glass containers for LEPH/HEPH, PAH and VOC analysis. Other analyses were carried out on samples from either bags or jars, as described above.

3.2.3 Soil Nutrients and Salinity

The sample collection and handling for soil nutrient and salinity parameters followed general methods described above. The soil analyzed for nutrient and salinity parameters was subsampled at the laboratory from the same jarred and/or bagged soils submitted as described above. Samples selected for analysis of these parameters were chosen to provide representative data for the various material classes (i.e., tailings, native within channel soils, and background soils) and spatial representation of the study area.

A total of 57 samples were submitted for analysis of nutrient parameters (available nitrate and nitrite, phosphorus, potassium, sulphate, mineralizable nitrogen, total carbon, total nitrogen, total organic carbon, anions, cation exchange capacity [CEC], and ammonium acetate extractable cations). Of these samples, 26 were considered representative of tailings material, 14 of native within channel soils, and 17 of native soil from background locations.

Samples were collected from mineral soil horizons and, where present, the forest floor (Litter, Fermented, Humus [LFH] layers) was carefully removed prior to sampling. Nutrients in the 26 tailings and 14 native within channel samples were selected to represent a diverse range of tailings and native soil types, and depositional environments.

At total of 60 samples were submitted for analysis of salinity parameters (i.e., pH, electrical conductivity, sodium, chloride, sodium adsorption ratio (SAR), exchangeable sodium percentage (ESP), theoretical gypsum requirement, and alkalinity). Of these samples, 26 were considered representative of tailings material, 17 of native within channel soils, and 17 of native soil from background locations.

3.2.4 Contact Tests

Soil pH and electrical conductivity were determined on soil water slurries (Hendershot *et al*. 1993; Janzen 1993) prepared by SNC-Lavalin following sample collection. Approximately 100 mL of distilled water was mixed with 50 grams (g) of lightly packed soil (i.e., 2:1 ratio by volume) in clean glass jars. The slurry was then agitated and let to stand for a minimum of 10 minutes, after which, the pH and conductivity were measured and recorded. Contact test data were then used to inform sample selection for laboratory analysis, as described in Section 3.4. Samples submitted to ALS were also analyzed for pH and electrical conductivity and methods are described in Appendix II.

3.3 Soil Physical Properties

3.3.1 Particle Size Determination and Soil Texture

The particle size distribution of soil samples was determined on laboratory prepared subsamples from jarred and/or bagged soil samples collected along soil transects. Soil particle size estimation in the field followed the USCS (Test Pit Logs, Appendix IV). Samples were analyzed using sieve and hydrometer methods described by ALS in Appendix II. The associated laboratory reports (Appendix V) describe the measured relative proportions of the various particle size fractions (gravel, sand, silt, clay) of the whole soil sample submitted for analysis (i.e., including gravel fractions). The laboratory used methods for particle size determination which considers soils passing the 0.063 micrometer (µm) sieve as silts and clays (fines) and gravel as anything retained on a 2 mm sieve.

SNC-Lavalin used the particles size results to estimate soil texture in general accordance with the Canadian System of Soil Classification (CSSC) (National Research Council of Canada 1998) which is determined based on the relative proportions of sand, silt, and clay fractions in soil passing a 2 mm sieve (i.e., soil fractions excluding gravel). To reflect this methodology, laboratory particle size results were “adjusted” for the purpose of determining soil texture and these data are reported only in Tables M and N (Section 5.5).

3.3.2 Bulk Density Sampling

The *in situ* bulk density assessment involved sampling the various material classes encountered throughout the SQIA, specifically the tailings, native within channel soils, and background soils. The surficial geologic origin of parent material was also interpreted for the within channel native soils (e.g., till, lacustrine deposits, etc.), as these units were specifically targeted for bulk density determination.

These units were targeted opportunistically and to achieve spatial representation along the channel. Due to the small sample size, the results are not intended to provide a thorough characterization of the units, but to provide an initial screening. Detailed descriptions of the surficial geology of the study area are provided in the HIA (SNC-Lavalin 2015b).

Where present, the forest floor and/or coarse woody debris were carefully removed to expose the underlying mineral soil. Soil at each location was excavated from a cylinder shaped hole (10 cm in diameter) to a depth of approximately 15 cm bgs (Photograph 18). Once the excavation was complete, the volume of the hole was measured to the nearest 5 mL with a graduated cylinder using density sand specified in the ASTM Standard Test Method for Density and Unit Weight of Soil in Place by the Sand-Cone Method (ASTM D1556 / D1556M-15). The sample ID and measured volume of the excavated material was recorded in the field. Sample locations were shifted approximately 30 cm in a random direction if the excavation was impeded due to the presence of cobbles or boulders. Sample location coordinates were recorded following the same method described for soil samples above.

The excavated soil for each sample was bagged, labelled, and shipped to SNC-Lavalin's geotechnical laboratory in Fort St. John, BC for analysis.

Upon receipt at the laboratory, the bulk density samples were analyzed using the ASTM D1556 test method. As required by ASTM D1556, samples were air dried following oven drying at 105 °C for 48 hours to achieve a constant dry mass. Samples were sieved through #10 sieve (2.00 mm mesh) to separate coarse fragments (i.e., coarse mineral and coarse organic material >2.00 mm in diameter) from the fine material. To calculate the bulk density of the fine material (i.e., <2.00 mm in diameter), mass and volume of coarse fragments were subtracted, respectively, from the mass and volume of the bulk sample. A particle density value of 2.65 megagrams per cubic metre (Mg/m^3) was used to determine the volume of coarse mineral material and a particle density value of 0.5 Mg/m^3 was used to determine the volume of any coarse organic material, using equation [1]:

$$Vol\ (m^3) = \frac{Mass\ (Mg)}{Particle\ density\ (Mg/m^3)} \quad [1]$$

Fine material bulk density was calculated as the mass of dry, coarse fragment-free soil per field measured volume of soil, where volume was also calculated on a coarse fragment-free basis, by using equation (2):

$$\text{Bulk Density } (Mg/m^3) = \frac{\text{Total Mass } (Mg) - (\text{Mass of Coarse Mineral } (Mg) + \text{Mass of Coarse Organic Material}) \ (Mg)}{\text{Total Volume } (m^3) - (\text{Volume of Coarse Mineral} + \text{Volume of Coarse Organic Material})(m^3)} \quad [2]$$

Laboratory reports for bulk density have been included in Appendix V.

3.3.3 Background Soil Sampling

Between September 3, 2014 and October 29, 2014, 19 background sample locations were established approximately 10 m beyond the lateral limit of the tailings affected area at alternating ends of each transect to assess soil background conditions with respect to total metals concentrations, nutrients, salinity, bulk density, particle size and rooting depth/size.

At background soil sample locations, test pits were advanced using hand tools (e.g., spade shovel, post-hole shovel, pick mattock, etc). Soil horizons (e.g., LFH, A, B, etc.) were identified in general accordance with the CSSC (National Research Council of Canada 1998). Soil samples were generally collected at discrete intervals from within the A horizon and also from underlying B horizons. If more than one B horizon was observed, suggesting varying underlying parent materials, additional samples were collected and the horizon (BII horizon) described independently. The dominant species of herbaceous, shrub, and tree communities, along with any evidence of contamination or stressed vegetation was documented and photographed.

Samples were collected using a clean hand trowel, placed into a clean, labelled polyethylene (Ziploc®) bag or laboratory supplied jars. Sample descriptions were logged in the field, including, particle size, colour using the USCS. Locations were recorded using both a GPS unit and on field sketches. The same sample collection, handling, and shipping procedures described in Section 3.2.1 were used for samples collected from background locations. Soil profiles are provided in the test pits logs (Appendix IV) and photographs of each soil profile are provided in Appendix I (Photographs 19 through 36).

The sampling locations were recorded in the field and were used in conjunction with aerial photograph imagery to support determination of the lateral extent of tailings. Refer to the HIA for detailed methods used to estimate the extent of the tailings affected area (SNC-Lavalin 2015b).

3.4 Summary of Sample Analysis Selection

SNC-Lavalin selected samples for laboratory analysis based on material class (tailings, native within channel, background) to identify physical and chemical composition anomalies in the receiving environment that may be associated with the tailings release event. Initial selections for analysis were based on field observations and contact test results. Some additional follow-up analyses were selected based on interim laboratory results.

Table G below provides a summary of sample selection rationale and number of sample selected for analysis by material type.

Table G: Summary of Soil Quality Analyses

<table>
<tr><th rowspan="2">Parameter</th><th rowspan="2">Sample Selection Rationale</th><th colspan="3">Number of Samples Analyzed (excluding QA/QC samples)</th></tr>
<tr><th>Tailings</th><th>Native Within Channel</th><th>Background</th></tr>
<tr><td>Total Metals + pH</td><td>• To represent the various soil types observed during sampling.</td><td>71</td><td>17</td><td>23</td></tr>
<tr><td>Nutrients</td><td rowspan="2">• To represent a diverse range of tailings and native soil types, and the more prevalent physical environments observed during the SQIA.</td><td>27</td><td>14</td><td>19</td></tr>

<tr><td>Bulk Density</td><td>• To represent a range of tailings and native soil types, and the various depositional environments observed during the SQIA.</td><td>9</td><td>8</td><td>4</td></tr>
</table>

Notes:

- Mine Processing Reagents included LEPH/HEPH, PAH, VOCs (carbon disulphide, 2-hexanone, MIBC, MIBK), glycols, xanthates.
- Salinity analysis includes paste pH, Conductivity, Nitrate, Chloride, Metals, SAR, Saturation Percentage, Theoretical Gypsum Requirement and Alkalinity.
- Nutrients analysis included Available Nitrate and Nitrite, Phosphorus, Potassium, Sulphate; Mineralizable Nitrogen, Total Carbon, Total Nitrogen, Total Organic Carbon, Anions, CEC and Ammonium Acetate Extractable Cations).

3.5 Statistical Evaluation

Simple statistics for minimum, maximum and average parameter concentrations were calculated in Microsoft Excel. Where data were less than their laboratory detection limit, a value of half the detection limit was used when calculating the average values of a given parameter. SNC-Lavalin used ProUCL 5.0 to estimate the 90th percentile concentrations, 95% upper confidence limits of the mean (95% Upper Confidence Limit of the Mean [UCLM]), and standard deviation. It was also used to generate histograms for data visualization purposes and to assess the data normality. Information on the statistical methodology used by ProUCL 5.0 is provided in the technical guide (US Environmental Protection Agency [EPA], 2013).

SNC-Lavalin estimated the distance in metres along Hazeltine Creek channel to the TSF of each soil transect, and then plotted chemical concentration versus distance from TSF. Relationships were assessed through regression analysis. Similarly copper and vanadium concentrations were plotted against the percent silt and clay and also assessed through regression analysis.

T-tests were also used to compare the differences between averages of material sample groups, for a number of analytical parameters, with significance assessed at P=<0.05.

Results of samples collected for QA/QC purposes were not included in the calculation of statistical parameters relating to soil quality data.

3.6 Quality Assurance / Quality Control

Sample collection and analysis were subject to QA/QC measures. Samples were collected in accordance with written POPs by trained field staff under the direction of senior project staff. SNC-Lavalin led all aspects of the SQIA. Blind field duplicate samples were collected at a frequency of approximately 1 in 10. QA/QC information, including a flowchart illustrating the document control methodology, and a data quality review is provided in Appendix III. The results of the data quality review are provided in the appropriate results and/or discussion sections. Laboratory QA/QC procedures and results are provided in analytical laboratory reports (Appendix V).

Five replicate samples and three silica sand field blank samples were also submitted for QA/QC purposes in support of SRK's tailings geochemical assessment (SRK 2015). Clean (blank) silica sand was filled into two clean 500 mL glass jars and one clean Ziploc® bag and submitted to ALS for analysis. Although provided in attached tables, the results related to replicates and silica sand field blanks are discussed in the SRK report. Field replicate sample locations were collected approximately 1 m in a random direction from their original sample location. Test pit logs are provided for replicate sample locations; however, the locations are not shown on the attached drawings given their small scale.

4 IMPACT ASSESSMENT METHODOLOGY

The methodology provided in the following sections outline types of information and data collected and how it was used to describe and discuss the potential soil quality impacts related to the TSF breach.

4.1 Lateral and Vertical Extents of Tailings

Field observations and aerial photograph imagery were used to interpret the spatial distribution of the tailings and deposited material along Hazeltine Creek. Test pit logs (Appendix IV) were used to record stratigraphic information observed in the field. Soil analytical results and contact testing were used to verify inferences regarding tailings distribution. Discussion on this is provided in Section 5.1.

The vertical extent of tailings deposition was determined through advancing a number test pits to a depth where native *in situ* soils were encountered. The stratigraphic information recorded on test pit logs was used to discuss the distribution of tailings, including their depth in relation to underlying native soils where these were intersected. The estimates of tailings depth and depth to native soils are provided in the context of limitations which affect the accuracy of the estimates, including the avoidance of certain unstable areas, and where native underlying soils were not intersected. The SQIA background sample locations, native depth measurements, and field observations supported the HIA estimate of the native within channel soil scour and tailings volume estimates. Further information on HIA methods used to estimate native within channel soil scour volumes and deposition volumes is provided in the HIA (SNC-Lavalin 2015b).

Semi-quantitative methods were used for estimating the lateral distribution of the tailings and provided an estimate of the surface area of the tailings-affected area. This was achieved through aerial photograph and topography interpretation coupled with field observations made during the SQIA and HIA field programs (SNC-Lavalin 2015b). The affected area boundary was further validated using GPS coordinates of background test pit locations collected approximately 10 m outside the affected area. Further information on HIA methods to determine the extent of the tailings affected area is provided in the HIA. Laboratory analytical results were also used to confirm the estimated lateral extent of tailings through comparison of tailings data versus soil quality data at background locations.

4.2 Soil Physical Impacts

A summary of the range of potential soil physical impacts is provided in relation to topsoil removal and/or their inundation with tailings. The results are based largely on field observations, including test pit logs (Appendix IV) to support the interpretations. The interpretation of the spatial extent of the physical impacts are reported in the context of the tailings affected area and the scour zone described in detail in the HIA (SNC-Lavalin 2015b) and shown on Drawings 621717-4-3-P1 to 621717-4-3-P11 (attached).

Stratigraphic data regarding forest floor and A horizon thickness and presence / absence are provided on test pit logs (Appendix IV) for the tailings affected areas both within and outside of the scour zone, along with comparisons to observed background conditions. The comparisons help to understand the conditions and potential impacts within the affected areas as they relate to the physical integrity of topsoil resources. The observed differences are discussed as they relate to soil nutrient availability, soil physical condition, and habitat for soil fauna and flora (i.e., microbial communities).

4.3 Soil Contaminant Chemistry

4.3.1 Regulatory Framework

In BC, soil standards exist, against which, comparison is possible to evaluate the human health and environmental health risk associated with a wide variety of parameters. As such, to screen for potential impacts, COPC identified to be associated with tailings and mine processing reagents (Section 2.7) were compared against the applicable standards, where available, contained within the *Contaminated Sites Regulation* (CSR), B.C. Reg. 375/96, including amendments up to B.C. Reg. 4/2014. The CSR includes generic, matrix, and site-specific comparative numerical standards for the concentrations of those substances in soil. For the purposes of determining applicable soil matrix numeric standards contained in Schedule 5 of the CSR, the following site-specific factors were determined to apply to the study area:

- Human Health Protection: Intake of contaminated soil (mandatory at all sites).
- Environmental Protection: Toxicity to soil invertebrates and plants (mandatory at all sites); and Groundwater flow to surface water used by freshwater aquatic life.

Considering the land use definitions contained in the CSR and the observed land use in the study area, CSR Wildlands (WL) was considered applicable to the study area. Since CSR standards for Wildlands are not available, the CSR specifies that Urban Park land use (PL) standards are appropriate comparison standards for soils within the depth of investigation for this report.

Although portions of the Study Area fall within the boundaries of the Agricultural Land Reserve (ALR) and BC Range Tenures 077614 and 077615, no signs of agricultural land use or evidence of grazing (animal sightings, feces, etc.) by domestic animals were observed during the field program. MPMC has confirmed that grazing is active along the Gavin Lake FSR. Grazing patterns and ranges of livestock in the area will be considered during the planned ecological and human health risk assessment program (Golder 2015).

As described in Section 3.5, SNC-Lavalin followed MoE Technical Guidance 2 titled *Statistical Criteria for Characterizing a Volume of Contaminated Material* (BC MoE 2009b) to characterize tailings and the statistical summary of results is included in Appendix VI. The resulting statistical parameters were considered in evaluating the distribution of various COPC in soil against CSR PL standards. In the Cariboo region of BC, regional background soil quality estimates are available for a number of the COPC and these are discussed, where appropriate. For instance, the regional background estimate for copper is 65 mg/kg and for vanadium it is 100 mg/kg (BC MoE 2010).

Concentrations of mine processing reagents including LEPH/HEPH, PAH, VOC, glycols and xanthates were compared against CSR PL standards, where available. Other soil chemical parameters analyzed for (e.g., pH, CEC, total carbon and inorganic carbon) are potentially important factors in determining the mobility and leachability of some of the COPC associated with the tailings (i.e., total metals). A detailed discussion on the metal mobility and leachability of sediments and tailings within the study area is provided in the Sediment Quality Impact Characterization report (Minnow 2015) and the Geochemical Characterization of Spilled Tailings report (SRK 2015), respectively.

4.3.2 Nutrients

Soil nutrient parameters were assessed to understand if the tailings or exposed mineral soils in areas of scour may be nutrient deficient posing potential challenges to soil productivity and site reclamation. Soil nutrients such as total nitrogen, total carbon, and mineralizable nitrogen are considered key indicators of soil productivity and are closely associated with soil organic matter content. Mineralizable soil nitrogen has been shown to be a useful indicator of soil productivity in forestry related studies (Powers 1980; Doran and Parkin 1994). It is a measure of the active fraction of soil organic nitrogen, which is largely responsible for the release of mineralizable nitrogen by the microbial community and its subsequent uptake by plants. Mineralizable nitrogen often correlates well with plant-available nitrogen and can be used to ascertain the presence of nutrient limiting conditions that could affect tree and other plant growth.

Total carbon, total nitrogen, available phosphorus, available potassium, mineralizable nitrogen, and CEC were specifically evaluated and compared between material classes to understand the potential impacts related to changes in soil nutrient status. The results of the nutrient assessment work are also discussed in the context of soil conditions at background locations and pre-disturbance soil data available for the areas of the Mine site and TSF area (Hallam Knight Piésold Ltd. 1995a).

The influence of soil pH on plant nutrient availability is also discussed. Specific impacts to terrestrial communities related to changes in soil chemistry are provided in the Terrestrial Wildlife and Vegetation Impact Assessment (TIA) (SNC-Lavalin 2015c).

4.3.3 Soil Salinity

Soil salinity can adversely affect performance of certain plant species through changes in nutrient availability and uptake, impacts to soil structure, and through osmotic imbalance (Brady and Weil 1996; McBride 1994). Tailings and subsoil salinity was assessed in two ways: 1) by comparison of chloride and sodium results to CSR PL standards; and 2) comparison of data for SAR, ESP, and electrical conductivity to literature values for evaluating soil sodicity.

4.4 Soil Physical Properties

4.4.1 Bulk Density

Although there are other factors that can influence site productivity, soil physical condition is considered to be an important indicator of soil quality. Measures such as bulk density are often used to assess soil physical condition (Schoenholtz *et al*. 2000) and it is also accepted as an important indicator in relation to forest productivity (Burger and Kelting 1999).

In the Hazard Assessment Keys for Evaluating Site Sensitivity to Soil Degrading Processes Guidebook, *soil compaction* is defined as an increase in soil bulk density that results from the rearrangement of soil particles in response to applied external forces (BC Ministry of Forests, 1999). Unweathered parent materials, largely free from soil forming processes, often lack soil structure and low organic matter content which influence soil-air-water-plant interactions. To assess potential impacts, the bulk density of the tailings and also of exposed or shallow parent materials within the Hazeltine channel was characterized for direct comparison to conditions at background locations and to literature values for potentially plant growth limiting bulk density.

Information regarding the physical condition of soil was also recorded on test pit logs (Appendix IV) as it relates to the density or consistency of the soil. This was a subjective measure that reflects the resistance of the soil to deformation, its relative cohesiveness, and the difficulty experienced during excavation. This information is discussed specifically in relation to the tailings material.

4.4.2 Particle Size and Soil Texture

The particle size distribution of a soil can influence the behavior and bioavailability of contaminants that may be present. It is also an important factor when considering the fate and transport of the COPC as it relates to soil permeability, erodibility, transport, and behaviour in aquatic systems (i.e., settling and dispersion).

When considering the effects of the bulk density on soil productivity, soil texture is an important consideration as it has been used successfully to estimate potentially growth limiting thresholds for a variety of plants (Daddow and Warrington 1983). Soil texture and coarse fragment content are often used to determine the potential susceptibility to compaction of a given soil, which can be important during soil handling and reclamation activities. For the purposes of the SQIA, the implications of the particle size results and soil texture are primarily discussed in the context of the soil bulk density results.

In relation to susceptibility to erosion, as well as potential terrestrial and aquatic impacts, particle size results are discussed in the HIA (SNC-Lavalin 2015b), TIA (SNC-Lavalin 2015c), and the Fish and Fish Habitat Impact Assessment (SNC-Lavalin 2015a), respectively.

5 ASSESSMENT RESULTS

Soil sample locations are shown on Drawings 621717-4-3-P1 to 621717-4-3-P11 (attached). Where applicable, the results are presented below by tailings, native within channel soil, and background material classes. Details on the corresponding tables, drawings and appendices are provided in each section.

5.1 *Lateral and Vertical Extents of Tailings*

The estimated lateral limits of the tailings affected area and of the scour zone are shown on Drawings 621717-4-3-P1 to 621717-4-3-P11 (attached). In total, approximately 2.34 square kilometres were affected by tailings as a result of the TSF breach. Approximately 42% of the area covered by tailings was found within standing forest, while the remaining 58% was found in areas where the forest and portions of native soils were removed (i.e., the scour zone).

The depth of tailings, where present, was measured at assessment locations, and the depth to native underlying soils was also recorded on test pit logs (Appendix IV). Native soil was intersected at 16 of the 18 soil transects completed within the tailings affected area, and at a total of 44 of the 68 test pits excavations. The average measured thickness of tailings was 0.25 m at assessment locations within the affected area; but, as noted below, the deposition was thicker in some areas. This estimate includes results that represent minimum tailings thicknesses at locations where native soils or bedrock were not intersected. Tailings were overlying variable mineral soils within the scour zone (Photograph 13), and somewhat intact forest soils outside of it (Photograph 12).

At a number of locations, tailings were probed below the base of test pit excavations in an effort to estimate the vertical extent of tailings. These results are described in the notes of test pit logs (Appendix IV). Areas where deeper tailings thicknesses were estimated included: 1) Polley Lake Plug in Upper Hazeltine Creek (0.8 m at ST18-02, 1.55 m at ST18-03); 2) Upper Hazeltine Creek (0.7 m at ST13-02, 1.3 m at ST11-02); and 3) Lower Hazeltine Creek (1.15 m at ST04-02, 0.8 m ST02-06). Photographs of select locations where deeper deposits of tailings were observed are provided in Appendix I (Photograph 10).

The observations from the SQIA regarding the lateral and vertical distribution of tailings were incorporated into the HIA estimate of tailings volume remaining in Hazeltine Creek (SNC-Lavalin 2015b). Results relating to the loss and/or inundation of topsoil resources in the tailings affected area are provided in Section 5.2, along with relevant tailings related observations.

5.2 Soil Physical Impacts

Soil resources were physically impacted by the breach in terms of loss of topsoil resources by erosion or their inundation with tailings. Observations relating to soil physical impacts were made during the SQIA and recorded on test pit logs (Appendix IV). This information was used to support estimating the zone of the tailings affected area, and the scour zone. The boundaries of these areas are shown on Drawings 621717-4-3-P1 to 621717-4-3-P11 (attached).

Within the scour zone, tailings were observed as surficial deposits over a range of substrates (e.g., parent materials) where forest floor and shallow soil horizons (e.g., topsoil) had been mostly removed, sometimes exposing parent mineral soil and/or bedrock (Photographs 13 and 15). Tailings thicknesses were on average 0.23 m thick, with less than a few cm measured covering parent materials at many locations, and up to and exceeding 1.55 m at others (maximum depth of tailings measured). No clear evidence of forest floor materials (LFH) were observed in these areas, and inferred A horizon soil material was only observed at four of 32 assessment locations where native soil was intersected, with variable tailings overburden thickness at these respective locations.

Tailings were also observed in areas outside of the scour zone, but still within what is considered the tailings affected area. A total of 16 soil sample test pits were advanced from outside of the scour zone yet within the boundary of the tailings affected area. Soil resources in these areas appeared to have been subjected to less erosion and at many of the locations, much of the topsoil and vegetation community appeared intact (Photographs 3). This type of environment represents approximately 136 hectares (ha) or 42% of the tailings affected area. Drawings 621717-4-3-P1 to 621717-4-3-P11 (attached) show the interpreted boundaries of the tailings affected area and interpreted limits of the scour zone. No clear evidence of LFH was observed in these areas, and A horizon material was identified at 11 of the 16 associated assessment locations. A summary of relevant soil stratigraphy data for tailings affected areas outside of the scour zone is provided in Table H. Soil stratigraphy data from background locations has been included for comparison purposes.

Table H: Summary of Soil Stratigraphy Data for Locations Outside of Scour Zone

Soil Stratigraphy	Thickness (m)			
	n	Minimum	Maximum	Average
Deposited Tailings	16	0.08	0.80	0.34
A Horizon	16	0	0.26	0.07
Background LFH	19	0.03	0.20	0.08
Background A Horizon	19	0	0.18	0.07

5.3 Field Screening Contact Tests

Field screening results of contact tests are provided in test pit logs (Appendix IV) and summarized by material class in Table I below.

Table I: Statistical Summary of Contact Testing Results by Material Class

Material Class	pH			Conductivity (µs/cm)		
	Minimum	Maximum	Average	Minimum	Maximum	Average
Tailings	6.98	9.44	8.54	17.5	876	318
Native Within Channel	6.24	8.63	7.23	23	285	99
Background	4.86	7.15	5.76	7.5	116	24.5

Contact testing results indicated tailings had basic pH levels, while native within channel samples were close to pH 7.0 (i.e., circumneutral) and background soils were typically more acidic. Tailings electrical conductivity on average was three to eight times higher than the averages of native within channel soils and background soils. Contact testing provided useful data that supported distinguishing between tailings and native soils, because the pH range of tailings was generally higher (i.e., more basic pH) and were measured with higher conductivity than within native soils at within channel and background locations (Section 3.2.4).

5.4 Soil Contaminant Chemistry

Results from the assessment of COPC identified in Section 2.7 in soil are presented by total metals and mine processing reagents in Table J.

5.4.1 Total Metals

A total of 71 tailings samples, 17 native within channel soil samples, and 23 background soil samples were submitted for laboratory analysis of total metals and pH. The results were screened against applicable CSR PL standards, where available. The results in comparison to the applicable standards are provided in Table 1 (attached). The laboratory analytical reports are included in Appendix V. Table J provides a summary of soil pH values and analytical results for COPC that exceeded the applicable standards in tailings (copper, vanadium, and arsenic) as well as parameters that exceeded CSR PL standards at native within channel soil and background soil assessment locations. Although concentrations of copper, vanadium, and arsenic were less than CSR PL standards at each of the native within channel soil and background soil assessment locations, the results have been included under their respective subheadings for comparison purposes.

Table J: Statistical Summary by Primary Contaminants in Soil

COPC	Number of Exceedances of CSR PL (mg/kg)	Minimum (mg/kg)	Maximum (mg/kg)	Average (mg/kg)	90th Percentile (mg/kg)	95% UCLM (mg/kg)	*Applicable CSR PL Standard* (mg/kg)
Tailings							
pH	-	7.51	9.09	8.50	8.88	8.56	n/a
Copper	71/71	**185**	**1,560**	**869**	**1,110**	**917**	150
Vanadium	24/71	106	**289**	187	**218**	194	200
Arsenic	1/71	7.54	16.5	11.2	13.1	11.6	15
Native Within Channel							
pH	-	5.95	8.48	7.30	8.33	7.62	n/a
Copper	0/17	6.28	86.7	36.1	64.3	44.7	150
Vanadium	0/17	2.04	100	59.7	88.5	70.6	200
Arsenic	0/17	0.43	14.7	6.98	10.0	8.43	15
Chromium	1/17	1	**61.7**	33.5	50.4	39.2	60
Background							
pH	-	4.69	7.13	5.62	6.54	5.86	n/a
Copper	0/23	5.98	135	35.6	74.5	49.1	90 - 150
Vanadium	0/23	40.2	133	70.0	103	78.4	200
Arsenic	0/23	3.06	14.2	6.98	11.3	8.10	15
Chromium	3/23	9.59	**108**	41.2	75.0	51.9	60
Manganese	2/23	170	**7,320**	930	1,188	1,418	1,800
Nickel	1/23	4.4	**104**	32.2	59.0	41.4	100
Selenium	1/23	0.2	**4.29**	0.39	0.59	0.80	3

Notes:

- The CSR PL standard for Human and Ecological Health considers the most stringent value.
- The CSR PL standard for Copper is pH dependent however since tailings and native within channel soils were above pH 5.5, the most stringent value is 150 mg/kg. A range is provided for background soils, since pH was measured below 5.5.
- Values exceeding CSR PL standards are shown in bold font.

Soil pH measured by the laboratory was consistent with contact test results where average tailings pH was basic, native within channel samples was circumneutral, and background soils were acidic.

The concentrations of copper and vanadium were consistently measured in tailings samples above their corresponding CSR PL standard (Table J above, Table 1, attached) throughout the study area and depth profile of the tailings. The average copper and vanadium concentrations of a subset of tailings samples representing the two observed tailings types (grey tailings [n=40] and magnetite sands [n=20]) were compared using a two tailed t-test to examine potential differences. The average concentration of copper in grey tailings (837.7 mg/kg) was not significantly different than that of magnetite sands (950.4 mg/kg) when assessed at a significance level of $P<0.05$ ($P=0.077$). Similarly, the average concentration of vanadium in grey tailings (184.6 mg/kg) was not significantly different than that of magnetite sands (190.7 mg/kg) when assessed at a significance level of $P<0.05$ ($P=0.478$). These results suggest that the concentration of copper concentrations may be influenced by differences between the two types of tailings. However, given the lack of statistical significance, and the concentrations of copper and vanadium relative to their CSR PL standards, their grouping is supported. Results and discussion presented herein treat tailings as one population. Analyzed soil samples collected from native within channel soil beneath tailings had concentrations of copper and vanadium below CSR PL standards.

Although the upper 95% UCLM concentration of vanadium in tailings is below CSR PL, the 90th percentile concentration (218 mg/kg) is marginally above the CSR PL standard of 200 mg/kg. In accordance with the MoE Technical Guidance document (No. 2) titled *Statistical Criteria for Characterizing a Volume of Contaminated Material*[1] (MoE TGD No. 2) (BC MoE 2009b), the concentration of vanadium in the tailings is considered above CSR PL standards.

The maximum concentration of arsenic was 16.5 mg/kg, which is slightly above CSR PL standard of 15 mg/kg in one tailings sample (ST17-03). However, following the methods of MoE TGD No. 2 for characterizing a volume of material, the tailings would be classified as meeting CSR PL standards. This interpretation is based on the tailings material being one population, the 90th percentile and upper 95% confidence limit of the average concentration are below the CSR PL standard, and the maximum concentration is less than twice the standard.

The concentrations of chromium, manganese, nickel and/or selenium in native soil were greater than corresponding CSR PL standards (Table J) at a few assessment locations from native within channel soils (ST15-02-02) or at background locations (ST12-01-01, ST12-01-02, ST13-01, and ST16-01-01). The concentration of these metals is attributed to naturally occurring background conditions. Each of the tailings samples analyzed contained concentrations of these metals less than the corresponding CSR PL standards supporting that the results are not associated with the tailings. These results for are not discussed further. The remainder of soil parameters in the samples analyzed contained concentrations of metals less than CSR PL. Consequently, copper and vanadium were the only metals considered contaminants of concern (COCs) in relation to the tailings. As a result, the discussion in Section 6.3 is limited to copper and vanadium.

[1] Technical Guidance Document 2: *Statistical Criteria for Characterizing a Volume of Contaminated Soil*, BC MoE, January 2009.

5.4.2 Mine Processing Reagents

A total of eight samples were analyzed for COPC associated with mine processing reagents. These included seven tailings samples representative of the two tailings types (i.e., grey tailings and magnetite sands). Samples were collected to achieve spatial representation by collecting samples from Upper Hazeltine Creek and Lower Hazeltine Creek. Sample ST15-02-02 was collected from native within channel soil below underlying approximately 0.1 m of tailings. The results in comparison to the applicable CSR PL standards are shown on Table 2 (attached). The laboratory analytical reports are included in Appendix V.

Concentrations of EPH, LEPH/HEPH, PAH, glycols and xanthates, were below laboratory method detection limits, and CSR PL standards where available. The concentrations of VOC compounds carbon disulphide, 2-hexanone, MIBC, and MIBK were also below laboratory method detection limits, and CSR PL standards where available.

5.4.3 Nutrients

The analytical results for soil nutrient parameters are provided in Table 2 (attached). Detailed laboratory results are provided in Appendix V. A summary of the results for key nutrient parameters is provided in Table K. For the purposes of calculating averages presented in Table K, values of half the method detection limit were used when results were non-detect. Results for soil pH are summarized in Table J above.

Table K: Summary by Key Soil Nutrient Results

Analytical Parameter	Tailings (n=27)			Native Within Channel (n=13*)			Background			
	Min	Max	Avg.	Min	Max	Avg.	n	Min	Max	Avg.
Total Carbon (%)	0.3	0.9	0.5	0.1	4.6 (44.2)	1.2 (4.2)	18	0.3	10.5	2.0
Total Nitrogen (%)	<0.02	0.028	0.011	<0.02	0.261 (2.63)	0.061 (0.244)	18	<0.02	0.667	0.117
Mineralizable Nitrogen (micrograms/gram [µg/g])	3	86	9	1.3	95 (350)	21 (44)	19	8	103	26
Cation Exchange Capacity (milliequivalents [meq]/100g)	2.55	30.4	7.28	4.21	28.3 (85.8)	12.2 (17.4)	18	6.1	81.3	18.9
Available Phosphate (µg/g)	<2	3.9	1.30	<2	9.4	2.31	18	1	293	41.17
Available Potassium (µg/g)	36	418	148.3	32	113	63.15	18	32	232	84.27

* Soil sample ST02-02 targeted an organic rich silt unit and is not directly comparable to other samples collected from mineral soil horizons. The maximum and average values presented outside of parentheses do not include the results for sample ST02-02 (n=13). Values inclusive of ST02-02 have been provided in parentheses for comparison (n=14).

Statistical differences in the average concentration of mineralizable nitrogen between and both native within channel soils and background soils were evaluated using one-tailed t-tests. Results indicated that the average concentration of mineralizable nitrogen in tailings was significantly less than both that of the native within channel soils (P=0.046) and background soils (P=0.003).

5.4.4 Salinity

The analytical results for soil salinity parameters are provided in Table 2 (attached). Detailed laboratory results are provided in Appendix V.

A summary of the results for key salinity parameters is provided in Table L.

Table L: Summary of Soil Salinity Results in Soil

Analytical Parameter	Tailings (n=27)			Native Within Channel (n=14)			Background (n=18)		
	Min	Max	Avg.	Min	Max	Avg.	Min	Max	Avg.
Saturated Paste Sodium (µg/g)	4.8	73.3	25.4	<2.00	16.0	4.05	<3.00	8.10	2.89
Saturated Paste Chloride (µg/g)	<2.0	19.8	7.4	<1.0	24.0	4.3	1.0	29.6	3.9
Electrical Conductivity (µS/cm)	132	2,320	953	71	956	298	35	363	101
Sodium Absorption Ratio	0.73	2.94	1.69	0.25	0.99	0.35	0.43	1.24	0.51
Exchangeable Sodium Percentage (%)	1.92	15.3	7.95	0.67	5.94	3.31	0.31	4.11	2.42

The soil samples from all material classes targeted for analysis of salinity related parameters contained concentrations of sodium and chloride less than their respective CSR PL standards of 200 µg/g and 90 µg/g.

5.5 Soil Physical Properties

5.5.1 Particle Size and Texture

The analytical results for particle size and their "adjusted" values used for estimating soil texture are provided in Table 1 (attached). Photographs of the different material types are provided in Appendix I (Photographs 10 to 13). The associated laboratory analytical reports are provided as Appendix V.

The estimated (adjusted) sand, silt, and clay contents of tailings samples are summarized in Table M, along with a list of associated soil classifications of the various tailings samples analyzed.

Table M: Summary of Tailings Soil Texture

Parameter	Tailings (n =20)		
	Minimum	Maximum	Average
Sand (%)	0.6	92.7	49.0
Silt (%)	6.8	80.2	41.4
Clay (%)	0.5	31.5	9.6
Gravel (%)	0.1	17.1	1.7
Soil Classification*	Loam (7), Silt Loam (5), Loamy Sand (4), Sandy Loam (2), Sand (1), Silty Clay Loam (1)		

* The number of occurrences are provided in parentheses.

A summary of particle size results for the various interpreted native within channel soil units is provided in Table N.

Table N: Summary of Particle Size Results for Native Within Channel Soils

	Till Units (n=9)			Lacustrine Unit (n=1)	Other Units* (n=3)		
	Min	Max	Average	Result	Min	Max	Average
Sand (%)	25.8	61.7	42.2	0.8	50.9	80.8	42.8
Silt (%)	31.5	58.1	42.4	66.7	13.4	42.8	27.0
Clay (%)	6.3	27.1	15.4	32.5	5.8	7.5	6.5
Gravel (%)	0	32.4	9.6	0	0	32.5	10.8
Soil Classifications**	Loam (4), Sandy Loam (3), Silt Loam (2)			Silty Clay Loam (1)	Sandy Loam (2), Loamy Sand (1)		

* The description "Other" refers to units not interpreted to be till or lacustrine parent material (i.e., sands and/or gravels with variable fines content).
** The number of occurrences are provided in parentheses.

5.5.2 Bulk Density

The analytical results for soil bulk density are provided in Table 4 (attached). Detailed laboratory results are provided in Appendix V. The various types of parent materials observed and targeted during the bulk density assessment were described for each of the samples to support interpretation of the bulk density results, and are shown on Table 4.

The bulk density results have been summarized in Figure A for each of the inferred material classes and parent materials assessed.

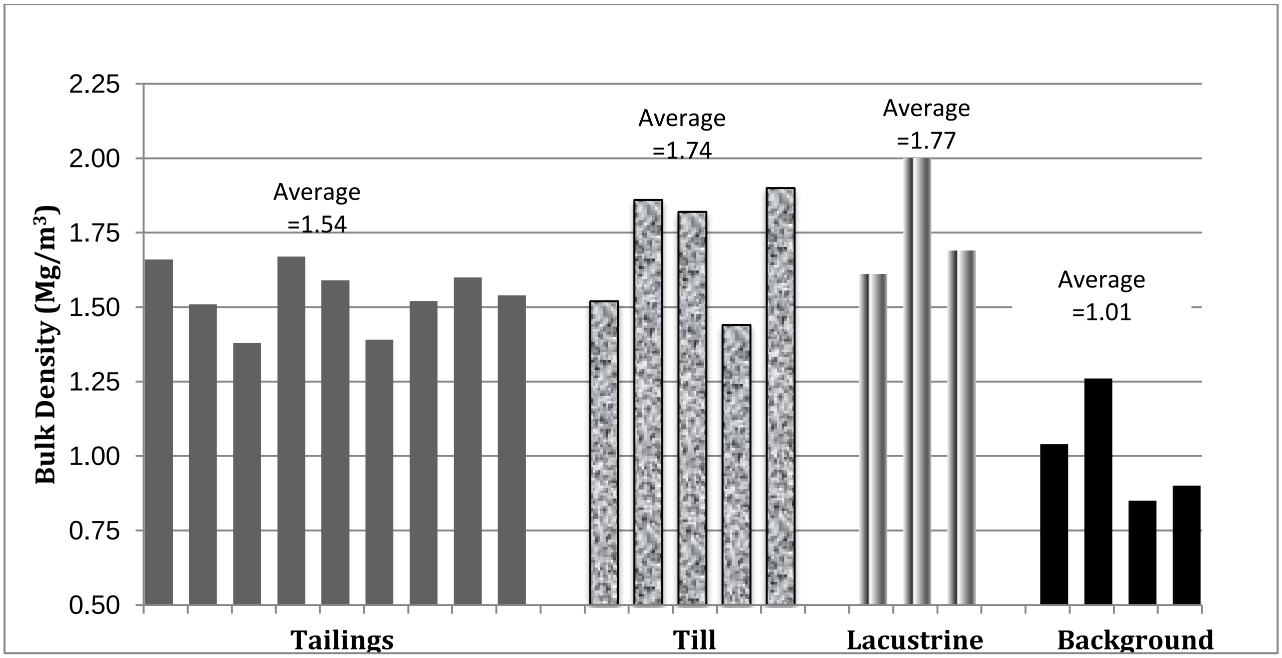

Figure A: Summary of Bulk Density for Tailings, Native Within Channel Soils and Background Soils

5.6 QA/QC

The results of the relative percent difference (RPD) calculations for the soil sampling program are included in Tables 1, 2 and 3 (attached). RPD for duplicate samples were below SNC-Lavalin's accepted RPD values except for sample pairs at locations ST01-09-03 and ST01-02-03, as summarized in Table O below.

Table O: Summary of Duplicate Samples Exceeding RPD Acceptance Criteria

Sample ID	Duplicate ID	Parameter	%RPD of Duplicate Sample
ST01-09-01	ST01-09-03	% Sand (2.00 mm - 1.00 mm)	94
ST01-02-01	ST01-02-03	Total Carbon (%)	162

The observed differences may be attributable to sample heterogeneity, laboratory error, or sampling error. Upon review of the data, and given the lack of comparison standards for these parameters, the differences are not considered to affect the conclusions of the report. Additional details from the QA/QC program can be found in Appendix III.

6 DISCUSSION

6.1 Lateral and Vertical Extents of Tailings

The SQIA measured tailings distribution by determining the lateral limits of tailings at 18 soil transects and by measuring the thickness of tailings at sample locations, where possible. The lateral and vertical extents of tailings were distinguished from native (*in situ*) soils through visually apparent differences in the field. The background samples collected outside of the inferred limits of the tailings affected area contained concentrations of copper and vanadium (COCs) less than CSR PL standards. These data support that at the time of sampling, the background locations had not been affected by the tailings, and further support the spatial estimates of the tailings affected area. Both the laboratory analytical results and contact testing data support the ability to visually discern differences between native soil from tailings in the field, which supports the use of the data set in estimating the extents of the tailings in the study area.

The estimates of tailings thickness indicate that results are variable both laterally across the channel, and along the length of Hazeltine Creek, particularly down gradient of Upper Hazeltine Creek. Our data set was not sufficient in size to analyze trends given the observed and measured variability, and attempts to quantify trends would likely be confounded by the limitations of the assessment. These limitations included the fact that certain areas were not sampled due to their inaccessibility and health and safety concerns (e.g., proximity to steep or cut slopes, saturated and deep tailings deposits, etc.).

Further discussion regarding the distribution of tailings in the study area, including in relation to fluvial geomorphological characteristics of the Hazeltine channel, are provided in the HIA (SNC-Lavalin 2015b), along with the methods and results of the spatial and volumetric estimates of tailings deposition.

6.2 Soil Physical Impacts

Topsoil resources in forested ecosystems are important to ecosystem function, as these horizons are host to the large majority of plant roots and provide habitat for soil flora and fauna. Soil fauna and flora (microbial communities) regulate organic matter turnover, contribute to plant available nutrient pools, and enhance soil structure. Topsoil also plays a role in the regulation of soil temperature and moisture which are important factors in plant performance and ecosystem function.

Within the scour zone, topsoil resources (LFH and/or A horizon) were not evident at all but four of the 32 assessment locations where native soil was intersected. This suggests that the upper portions of the soil horizons were largely eroded as a result of the TSF breach. Although tailings thicknesses were not determined at every assessment location due to limitations related to assessment methodology and site conditions, an average tailings thickness of 23 cm was estimated, although it was observed to range up to 1.55 m. This average value may be low due to the full depth of tailings not being measured at all locations and some depositional environments not being investigated due to safety concerns. These measurements indicate that rooting depths at many locations within the scour zone where tailings are relatively thin, are likely to extend to the underlying mineral soil horizons making their characterization important with respect to indicators of soil productivity (refer to Sections 6.4).

At locations outside of the scour zone within the tailings affected area, native soils were intersected at twelve of 16 assessment locations. The A horizon thickness at the twelve locations ranged between 0 cm and 26 cm, with the maximum thickness measured at ST02-02, an area where thick organic rich soils were observed. Excluding the assessment location ST02-02, the average A horizon thicknesses were similar between the locations outside of the scour zone (8 cm) and those at the background locations (7 cm).

The deposited tailings thickness was variable (0.08 m to 0.8 m) in the areas outside of the scour zone, and was approximately 0.34 m thick on average. Based on the observed depth of topsoil inundation at these locations, the topsoil will likely continue to act as a source of available nutrients for plants and habitat for soil fauna to varying degrees. The contributions of the inundated topsoil to plant available nutrients and habitat for soil fauna would be expected to diminish as tailings thickness increases, and they become physically further from the active rooting zone. The range of potential impacts to plants from tailings inundation of topsoil resources will likely vary depending on the rooting depths of the species.

Where topsoil loss has occurred, the habitat of various soil organisms has been directly impacted by removal or alteration. In relation to soil quality, the changes to topsoil distribution will affect the lower trophic level organisms that are largely responsible for the decomposition of organic matter and nutrient cycling. The changes may have long term impacts related to plant nutrient availability and ecological function. A detailed discussion on potential ecological impacts of the breach related to plant and animal communities is provided in the TIA (SNC-Lavalin 2015c), and will be further assessed in the planned ecological and human health risk assessments (Golder 2015).

Changes to soil thermal and moisture regimes are likely to have resulted through the loss of topsoil and forest floor resources which contribute to their regulation in forested ecosystems. These changes typically have the most pronounced affects during periods of higher or lower than normal precipitation or temperatures when soils conditions become potentially growth limiting (e.g., moisture contents at permanent wilting point, high soil strength, reduced air-filled porosity, etc.). Their study was outside of the scope of the SQIA as one time measurements, particularly at the end of the growing season, would not be expected to yield meaningful results.

Due to the geotechnically unstable nature of the channel at some locations, ongoing changes to soil resources related to slope failure and mass wasting would be expected. Such impacts include further topsoil loss, inundation and/or mixing with subsoil during failure events.

Discussion on the potential impacts related to the loss of topsoil and its inundation in the tailings affected area are provided in Section 6.3.4 in the context of soil nutrient and soil physical properties.

6.3 Soil Contaminant Chemistry

The following discusses the results for COC identified to be associated with the tailings assessed as part of the SQIA.

6.3.1 Copper and Vanadium

The SQIA identified concentrations of copper and vanadium above their corresponding CSR PL standards throughout the study area and these metals are considered to be associated with the entire volume of tailings material based on the distribution of the copper and vanadium data suggesting they are representative of a single population. These COC appeared to be evenly distributed vertically throughout the entire study area. Vertically stratified sampling did not identify spatial trends that would suggesting these contaminants were stratified at the time of the sampling event. The environmental quality of underlying native within channel soils (less than CSR PL) indicates that at the time of sampling, these COC had not affected underlying (*in situ*) soils at the locations targeted for sampling. The potential for metal leaching from tailings over time is discussed in the Geochemical Characterization of Spilled Tailings report (SRK 2015).

Data exists from prior to mine development (Hallam Knight Piésold Ltd. 1995a) that suggests copper in mineral soil horizons in the area of the mine and mill site (copper concentration ranged from 86 mg/kg to 1,980 mg/kg; average of 521 mg/kg) contained concentrations of copper greater than CSR PL standards, and even at concentrations greater than the highest copper values observed in tailings samples (1,560 mg/kg in ST17-03), while samples collected near the TSF contained copper concentrations below CSR PL. These data are likely most relevant to locations near the Mine and mill site, whereas background data collected during the SQIA is more relevant as distance from the Mine and mill increases. The pre-disturbance data (Hallam Knight Piésold Ltd 1995a) does highlight that native soils in the region may contain concentrations of copper within or above the range observed for the tailings, likely when in close proximity to mineralized bedrock or soils that have formed on them.

To assess horizontal spatial trends, the concentrations of copper and vanadium in tailings were plotted against the estimated distance of each sample from the TSF, as illustrated in Figure B below. The coefficients of determination (R^2 value) were approximately 0.25 for both metals suggesting a weak trend of decreasing concentration of copper and vanadium as distance from the TSF increases. This may be a result of increased mixing between tailings and native within channel soils (dilution) as distance from the TSF increases. Field observations of scouring in the Upper Hazeltine Creek and Hazeltine Canyon areas, along with the results of the HIA support this interpretation. The potential changes in copper concentration with distance from the TSF does not affect the interpretation of the results in relation to applicable CSR PL standards.

However, the observed trend for vanadium suggests that it may be occurring in soil at concentrations exceeding CSR PL standards at greater frequencies in Upper Hazeltine Creek compared to the Lower Hazeltine Creek area. This is supported by results which indicated that the concentration of vanadium in tailings samples collected from Upper Hazeltine Creek was above the CSR PL standard in 21 of 46 (46%) samples, while only 3 of 25 (12%) samples contained concentrations above the standard in Lower Hazeltine Creek.

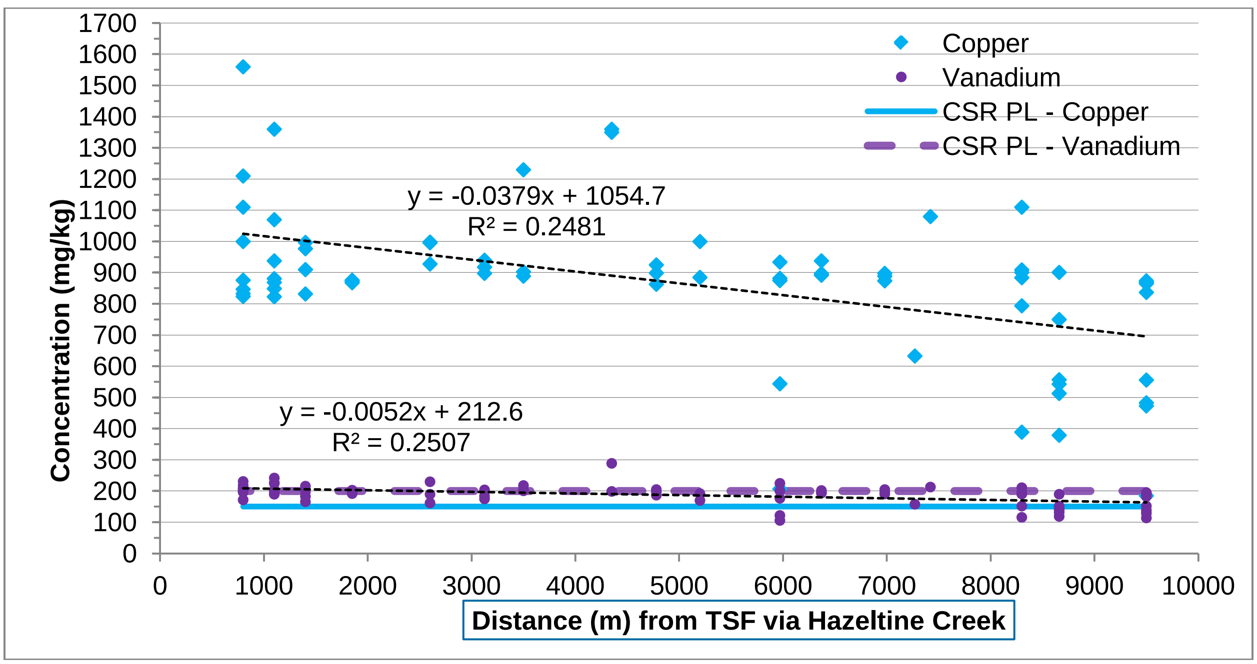

Figure B: Total Copper and Vanadium versus Distance to TSF

To evaluate the potential influence of tailings particle size, copper concentrations were plotted against combined silt and clay contents (% silt + % clay). The effect size of combined silt and clay content on copper and vanadium concentration was low (R^2=0.04 and R^2=0.11, respectively) suggesting the concentration of these COPC are not strongly associated with particle size.

The average depths of tailings samples were also plotted against the concentrations of copper and vanadium in tailings to examine for potential vertical trends in contaminant distribution. The low R^2

values (R^2=0.0005 for copper, R^2=0.0327 for vanadium) support that the contaminants were not stratified vertically.

The distribution of these two metals is generally considered to be consistent with the distribution of tailings throughout the study area. Accordingly, the discussion on the lateral and vertical extents of tailings is considered directly applicable in understanding the distribution of copper and vanadium at the site. Additional relevant information on the distribution of tailings is contained within the HIA (SNC-Lavalin 2015b).

6.3.2 Standards for Environmental Protection

This discussion summarizes how CSR PL standards for copper and vanadium are derived, and also discusses the fate and transport of these contaminants in the environment. Further discussion on the reactivity and mobility (leachability) of metals in the environment was assessed and reported by SRK as part of geochemical studies (SRK 2015).

6.3.2.1 Copper

The BC CSR Schedule 5 Matrix Numerical Soil Standards provide standards for both protection of human health and the environment, specific to the exposure pathway of concern. Since a standard for Wildlands is not available, the Urban Park standard is applicable to soils from 0 m to 3 m bgs, while Commercial standards are applicable to soils at depths greater than 3 m bgs. The most conservative soil standard for copper, applicable to either human health or environmental protection, was determined to be the standard for Toxicity to Soil Invertebrates and Plants at 150 mg/kg; this standard was used for comparison to concentrations of copper in affected soils.

In general, the standards for Toxicity to Soil Invertebrates and Plants were derived by the Contaminated Sites Soil Task Group (CSST) through the use of the sensitive measurement endpoint data from key receptors, considered to act as predictive sentinel species (BC MoE 1996). Primarily, endpoints used in standard derivation included mortality, reproduction and growth, with raw data for these endpoints obtained from the Canadian Council of Minister of the Environment (CCME) Ecological Health Substance Assessment documents. In determining the critical ecological receptors and pathways for use in deriving environmental protection matrix standards, CSST considered the land use and relevant direct exposure pathways. For Agricultural, Residential and Urban Parkland uses, the concentration corresponding to the more stringent of the LC20 (the concentration at which 20% of tested organisms experienced mortality) and EC50-NL (the concentration at which 50% of tested organisms experienced a non-lethal effect) values was chosen as the appropriate Toxicity to Soil Invertebrates and Plants soil quality matrix standard.

6.3.2.2 Vanadium

The BC CSR Schedule 4 Generic Numerical Soils standards provide a generic numerical value considered to be protective of both human health and the environment. Since a standard for Wildlands is not available, the Urban Park standard is applicable to soils from 0 m to 3 m bgs, while Commercial standards are applicable to soils at depths greater than 3 m bgs. The BC CSR Schedule 4 guideline of 200 mg/kg for vanadium was used for comparison to levels of vanadium measured in area of impact soils. Though the BC CSR guideline is considered to be protective of both human and ecological receptors, specific rationale behind the derivation of these standards is not provided.

The BC CSR standard of 200 mg/kg is consistent with the interim remediation criteria for vanadium, proposed by the CCME in 1991. While the rationale for the selection of this CCME guideline is not available, the interim guidelines from 1991, were based on existing guidelines in other jurisdictions (such as BC MoE, Ontario MoE, or Alberta Tier 1 criteria); these guidelines would not take into account any toxicity testing or research developments that occurred after 1991, and are considered potentially outdated.

Considering that the 95% UCLM of vanadium concentration in tailings was less than the CSR PL standard, and that any remedial efforts directed towards managing risks associated with elevated copper would be expected to manage risks posed by vanadium in concurrence, vanadium is considered a secondary COPC.

6.3.3 Mine Processing Reagents

The concentration of EPH, LEPH/HEPH, PAH, glycols and xanthates in tailings samples targeted for analysis were less than laboratory method detection limits and corresponding CSR PL standards. The VOC compounds carbon disulphide, 2-hexanone, MIBC and MIBK were also measured in each of the samples at concentrations below laboratory method detection limits. Results were not unexpected given that these COPC would be expected to have been consumed during mine processing, ending up in the mineral concentrate shipped for smelting, and/or have been biologically degraded to varying degrees within the TSF.

6.3.4 Nutrients

Soil nutrient estimates for pre-disturbance mine and TSF area soils (Table E) and background mineral soils (Table K) were similar within the study area. Although total carbon includes inorganic fractions, the vast majority of background soils studied as part of the SQIA contained low amounts of inorganic carbon making its comparison to the pre-disturbance soil organic matter content data reasonable, and helps to validate the background nutrient data set.

Mineralized nitrogen is typically correlated with total carbon and total nitrogen values and is also considered an appropriate indicator for soil quality in relation to plant available nitrogen. Values of mineralizable nitrogen below 10 µg/g to 17 µg/g have been associated with poor tree performance in some conifer species (Powers 1980). Soil at background locations contained mineralizable nitrogen concentrations between 8 µg/g and 103 µg/g with an average of 26 µg/g. The average concentration of mineralizable nitrogen in tailings samples was 9 µg/g, and values under 10 µg/g were measured at 24 of the 27 locations assessed. The average concentration of mineralizable nitrogen was less in tailings than in soils at both background (P=0.003) and native within channel (P=0.003) assessment locations.

The average concentration of available phosphate was 1.3 µg/g, and was less than laboratory method detection limits (<2 µg/g)[2] at 23 of 27 tailings samples. This is in contrast to an average concentration of 41 µg/g at background locations. The availability of phosphate is influenced by soil pH as it typically becomes increasingly insoluble with a rise in pH. The range in values of available potassium between the material classes were similar, with average values of 148 µg/g measured in the tailings in comparison to 84.3 µg/g measured in background soils. The minimum concentration of available potassium in tailings (36 µg/g) was similar to that measured in native within channel soils and at background locations (32 µg/g). On average, tailings contained approximately double the combined average concentration of available potassium of the native within channel and background soils. These results suggests potassium is not at growth limiting concentrations in the tailings.

In comparison to deeper subsoils, shallow mineral soils are typically enriched with respect to many key plant available soil nutrients originating in upper soil horizons from the decomposition of organic materials present in LFH and A horizon layers. Nutrient conditions appear to be variable for native within channel soils with values of mineralizable nitrogen ranging between 1 µg/g and 95 µg/g. The variability is likely related to the degree of scouring that occurred at a given location which affected the depth from the original ground surface at which samples were collected. In areas where scoured subsoils are exposed or thinly inundated by tailings, they may serve as potential rooting media for plants, and their nutrient status will likely depend largely on the depth from original grades and the degree to which topsoil resources were affected (refer to Section 4.2).

The average pH of the tailings was approximately 8.5 with values ranging between 7.51 and 9.1. The elevated pH of the tailings is likely attributable in part to the use of lime as a mine processing reagent. These values are typically considered indicative of moderately to strongly alkaline soils. In comparison, the average pH at the background locations was 5.62, a value typical for upper soil horizons in forested ecosystems where the yearly addition and decomposition of litter causes acidification. The average pH of the native within channel soil was also variable with an average of 7.29, with differences between native within channel and background soils likely attributable to the degree of scouring and removal of lower pH topsoil.

[2] Concentrations equal to half of the laboratory detection limit was used to calculate the average which explains why the minimum reported value exceeds the average.

The results indicate that for some plant species, growth limiting conditions with respect to nutrients may be encountered within the tailings deposits, and also at some locations of exposed mineral subsoil within the tailings affected area. Many pioneer plant and shrub species, including some conifers such as lodgepole pine, are adapted to nutrient poor soil conditions (Kranabetter *et al.* 2006) and their establishment and performance may not be influenced to the same degree by the nutrient-related conditions. Fertilization and/or addition of nutrient rich or organic amendments are often considered to improve the nutrient status of deficient soils. Measuring foliar concentrations of emergent vegetation allows for a more direct evaluation of the effects of soil nutrient status on vegetation performance.

In addition to the nutrient parameters discussed above, the availability of micronutrients such as boron, cobalt, copper, iron, manganese, and zinc are known to be reduced in soils with elevated pH similar to that of the tailings. Additional investigation would be necessary to ascertain any potential nutrient deficiencies related to these micronutrients; however, this is likely better suited for evaluation upon establishing reclamation objectives and understanding the range of materials on which re-vegetation efforts will be undertaken.

The potential influence of the change in pH on the plant communities in the study area is further discussed in the TIA (SNC-Lavalin 2015c).

6.3.5 Salinity

The concentration of sodium and chloride parameters in the various material classes, including tailings, were less than their respective CSR PL standards indicating they are not considered COCs.

The soil salinity of the tailings, native within channel soils, and background soils was also evaluated against literature values for classifying them as normal, saline, sodic, or saline-sodic soils (Brady and Weil 1996) based on their pH, electrical conductivity, SAR, and ESP. At background and native within channel soil assessment locations, each of the samples targeted for analysis were considered within the range of normal soils.

On average, tailings also fall within the normal range. However, approximately half of the samples have pH values greater than 8.5. Soils with pH values above 8.5 are generally considered moderately to strongly alkaline. However, when values of soil electrical conductivity, SAR, and ESP are within the range of normal soils, soils with pH values over 8.5 are not classified. This is given that the exchange complex of soils with elevated pH is typically dominated by sodium, which is not the case for the vast majority of the tailings materials. The average exchangeable sodium in the tailings was 0.54 meq/100g and was less than method detection limits (<0.5 ceq/100 g) at 12 of the 27 sampling locations.

A discussion on the influence of pH on nutrient availability is provided in Section 6.4 above. A detailed discussion on the importance of pH as it relates to the geochemistry of the tailings and mobility of the metals is provided in the Geochemical Characterization of Spilled Tailings report (SRK 2015).

6.4 Soil Physical Properties

Various studies have focused on identifying growth limiting bulk density (GLBD) thresholds for a variety of plant and tree species and some of these values have been used as criteria in evaluating the quality of soils to support sustainable plant growth (Daddow and Warrington 1983). Daddow and Warrington used the "Average Pore Radius" as the only variable driving GLBD, based on the theory that most soil pore diameters at the GLBD were less than the diameter of growing roots which can restrict their elongation. Daddow and Warrington's model was based on research typically conducted on sites with coarse fragment (>2.00 mm) contents less than 10%, which confined its applicability to similar types of soils.

Some studies suggest root growth and development may become restricted at or above a bulk density values of approximately 1.4 to 1.6 gram per cubic centimetre (g/cm^3) depending on soil texture (Brady and Weil 1996; Bulmer and Krzic 2003). This is a result of elevated soil mechanical resistance or strength often exhibited by soils with high bulk density, particularly when soils are dry; as soil moisture strongly influences soil strength. Zou *et al*. (2000) demonstrated that soils with higher bulk densities experience quicker rates of strength increase during drying. Bulk density also is an indirect measure of the porosity of soil and therefore can indicate differences in soil structure, particularly between similar soils.

The estimated average bulk density of the tailings samples was 1.54 Mg/m^3, which is based on an average assumed particle density of 2.65 Mg/m^3. Based on the range in textures of the tailings, and using GLBD estimates provided by Daddow and Warrington (1983), plant growth may become limited at values of bulk density as low as 1.4 Mg/m^3 (Silty Clay Loam) and at values up to and exceeding 1.75 Mg/m^3 (Loamy Sand, Sands). When considering the average texture of the tailings material, the GLBD would be equal to a value between 1.55 Mg/m^3 and 1.60 Mg/m^3, suggesting that the tailings materials are, on average, not in a potentially growth limiting state.

The assumed particle density used to calculate the tailings bulk density values is likely biased low given it assumes soils are derived from typical parent geologic materials, rather than originating from the processing of mineralized and metal enriched ore bodies being targeted by mining activities. The use of lower than actual particle density values in Equations 1 and 2 (Section 3.3.2) results in overestimates of bulk density being calculated. Although field observations such as resistance experienced during test pit excavation and sampling would have been strongly influenced by field soil moisture conditions, observations suggested tailings were generally loose or soft and not in a compacted state. These observations support the interpretation that bulk density estimates may be biased high for the tailings materials. Additional investigation to determine the particle density of the tailings (e.g., through pycnometry) would be necessary to confirm this interpretation.

Based on the Hazard Assessment Keys for Evaluating Site Sensitivity to Soil Degrading Processes Guidebook, the tailings would be considered to have compaction hazard ratings ranging between low to very high depending on the soil moisture regime. Susceptibility and resiliency to compaction is also influenced by moisture content, soil organic carbon, and texture (Smith *et al*. 1997). This information is provided in the context of possible future reclamation activities and may be important for planning purposes.

Native within channel soils were also targeted for bulk density determination. For soils characterized as till, using GLBD estimates provided by Daddow and Warrington (1983), plant growth may become limited at values of bulk density as low as 1.45 Mg/m^3 and at values up to 1.65 Mg/m^3. This estimate of GLBD thresholds is provided in consideration of the range in soil textures measured for samples representative of till units (Table N). The till units had bulk density values both above and below this range, and have an average bulk density of 1.74 Mg/m^3, which is greater than the estimated GLBD.

For the lacustrine soils, the GLBD estimate is approximately 1.42 Mg/m^3. The bulk density values of the three soil samples collected from lacustrine deposits were greater than the estimated GLBD, and their average was 1.77 Mg/m^3. In comparison, the average bulk density of the four samples collected from background locations was approximately 1.01 Mg/m^3.

The occurrences of morainal tills were expected to be predominant in the Upper Hazeltine Creek study area, and in the Hazeltine Canyon, based on surficial geological survey data (Section 2.2). The results of the SQIA support the distribution of tills in these reaches, but also identified glaciolacustrine deposits in the Hazeltine Canyon, typically observed below the till deposits, and also exposed at surface in the Lower Hazeltine Creek area (near transects ST02 and ST03). The distribution of observed surficial geological deposits is discussed in greater detail in the HIA (SNC-Lavalin 2015b).

Although the study has a relatively small sample size, the results suggest that potentially growth limiting conditions may be experienced by some plant species at locations where tills and lacustrine deposits are exposed, and where, correspondingly, topsoil resources have been eroded. A study evaluating the effects of physical soil rehabilitation identified that lodgepole pine (*Pinus contorta*) performance on fine textured soils with elevated bulk density, in contrast to the white spruce (*Picea glauca*) endemic to the study area, was not affected by improving soil physical condition (McConkey *et al*. 2012). Kranabetter *et al*. (2006) found similar results with respect to lodgepole pine in the interior of BC. These differences highlight that the influence of soil physical condition on plant performance is a function of plant physiology and other factors including climate and soil moisture regime as these influence the complex soil-air-moisture-plant relationships. Various early successional species are adapted to establish on poor substrates with respect to soil physical condition.

Although drainage is not entirely governed by soil texture, the presence of coarse fragments tends to improve drainage and soil gas exchange due to connectivity of pores. Coarse grained soils tend to have higher GLBDs (Daddow and Warrington, 1983) and they exhibit a greater ability to recover from compaction (Page-Dumroese *et al*. 2006), as compared to fine-textured soils. For these reasons, the study focused on soils with lower coarse fragment contents as exhibited by the various till and lacustrine deposits.

Coarse grained soils were described in detail at a number of "observation" points along the channel during the bulk density sampling (Table 4, attached). These locations are shown on Drawings 621717-4-3-P1 to 621717-4-3-P11 (attached) with sample ID prefixes "OBS". These locations were not sampled due to their high estimated volumetric (v/v) coarse fragment content (i.e., greater than 50% v/v). Although locations with elevated estimated volumetric coarse fragment content (>50% v/v) were observed near the Polly Lake Plug (ST16) and above the Hazeltine Canyon (ST08), soil texture and coarse fragment content at native soil assessment locations within the scour zone appeared more variable in the Lower Hazeltine Creek area than in others. Native within channel soils in this area included tills, lacustrine deposits and a range of sand and / or gravel units with variable cobble and boulder content.

7 CONCLUSION

The following summarizes the key conclusions of the SQIA based on findings of the background review and soil sampling and analysis carried out between September 3, 2014 and October 29, 2014:

- Based on background information related to surficial geology, the pre-disturbance conditions of the study area were generally described as being dominated by glacial morainal and glaciofluvial deposits. Field observations and sampling supported these descriptions, but also identified fine textured glaciolacustrine deposits, most often observed in the lower reaches of Hazeltine Creek.
- Tailings were observed to have been deposited in what is referred to as the scour zone (135.9 ha) where topsoil resources had been removed to varying degrees, and outside of the scour zone in areas with standing vegetation (98.5 ha).
- The loss of topsoil has altered the habitat for soil flora and fauna, and related soil ecological functions such as nutrient cycling are likely to have been impacted. An evaluation of available nutrients (i.e., mineralizable N) indicate that tailings and exposed (or shallow) mineral subsoils may present growth limiting conditions for some plant species, and this is likely to be influenced by the degree to which shallow soils (i.e., topsoil) have been scoured and / or inundated by tailings.
- The tailings samples contained concentrations of total metals parameters less than CSR PL standards with the exception of copper, vanadium, and arsenic. Arsenic was measured in a single sample at a concentration marginally greater than the CSR PL standard, and statistical methods (BC MoE 2009b) indicate the tailings, on a statistical basis, are not considered to exceed the CSR PL standard for this parameter. The results were considered generally consistent with pre-release tailings chemistry
- Considering that the 95% UCLM of vanadium concentrations in tailings was less than the CSR PL standard, and that any remedial efforts directed towards managing risks associated with elevated copper would be expected to manage risks posed by vanadium in concurrence, vanadium is considered a secondary COPC.
- The concentrations of targeted analytical parameters associated with mine processing reagents were less than corresponding CSR PL standards and minimum laboratory method detection limits in the seven tailings samples and the single native within channel soil sample submitted for analysis.

- Soil samples collected from native soils beneath the tailings and from background locations outside of the tailings affected area contained concentrations of copper and vanadium less than corresponding CSR PL standards. Pre-disturbance (pre-mine construction, circa 1995) soil chemistry results from samples collected from mineral soil in the area of the Mine and mill site contained concentrations of copper between 86 mg/kg and 1980 mg/kg, which includes values that exceed the maximum observed value in tailings and the corresponding CSR PL standard. These results highlight that in a regional context, soils containing elevated concentrations of copper are present.
- Using regression analysis, copper and vanadium concentrations were determined to not be strongly influenced by sample depth or texture (i.e., combined silt and clay fractions). A weak trend of decreasing concentration of copper and vanadium with distance from the TSF was observed. This trend does not change the interpretation of the results with respect to the CSR PL standard for copper; however, suggests that vanadium may not be present at concentrations greater than CSR PL standards in the Lower Hazeltine Creek area.
- The interpretation of the distribution of tailings within the study area is considered directly applicable to understanding the distribution of the COC associated with the tailings (i.e., copper and vanadium).
- The bulk density values measured for till and lacustrine deposits suggests that where these soils are exposed or shallow, potentially growth limiting conditions with respect to soil physical condition may be present for some plant species.

8 ACKNOWLEDGMENTS

This SQIA report was written by Trevor McConkey, M.Sc., P.Ag. (Project Manager) and Daniel Schneider, R.P.Bio., P.Ag., with senior technical review provided by Alan Walker, M.Sc., P.Eng., CSAP and Project Sponsor Gordon Johnson, M.Sc., P.Eng. Other SNC-Lavalin contributors included Andrew Botfield, PhD., who reviewed mine processing reagent records, historical tailings inventory and pre-release chemistry data for determination of Contaminants of Potential Concern (COPC). Lindsay Du Gas, M.E.T., R.P.Bio., provided a discussion on the environmental quality standards of COC. Graeme Paterson, EPt., and Craig Pinnell, E.I.T assisted in statistical calculations and a review of project data for quality assurance and quality control (QA/QC) purposes. Natalie Neufeld assisted in data management and in preparation of data summary tables.

The field program was executed by Trevor McConkey, Daniel Schneider, Andrew Dickinson, Vladimir Danov, M.Sc., and Tyler Anderson, EP (SNC-Lavalin). Field work was carried out in conjunction with SRK personnel Stephen Day, P.Geo., Chris Kennedy, M.Sc., P.Geo., and Saskia Nowicki, M.Sc., of SRK Consulting (Canada) Inc. Russell Gibson of Imperial Metals Corporation and Tim Worthington of MPMC were instrumental in assisting the field crews with logistics and in obtaining safe access to the study area.

Associated ALS files: L1518225, L1519001, L1520490, L1522556, L1540219.
All terms defined within the body of SNC-Lavalin's report.
< Denotes concentration less than indicated detection limit or RPD less than indicated value.
- Denotes analysis not conducted.
n/a Denotes no applicable standard.
RPD Denotes relative percent difference.
* RPDs are not normally calculated where one or more concentrations are less than five times MDL.

BOLD Concentration greater than CSR Urban Park Land Use (PL) standard.

[a] The site-specific factors used for determining the matrix standards for this site include: intake of contaminated soil, groundwater used for drinking water, toxicity to soil invertebrates and plants, and groundwater flow to surface water used by freshwater aquatic life (whichever is most stringent).
[b] Standard varies with pH.

TABLE 1 (cont'd): Summary of Analytical Results for Physical Parameters, Particle Size and Total Metals in Soil

Sample Location	Sample ID	Sample Type	Sample Date (yyyy mm dd)	Depth Interval (m)	Miscellaneous Parameters: pH (pH)	Total Organic Carbon (%)	Total Inorganic Carbon (%)	Inorganic Carbon (as CACO3 Equiv) (%)	Moisture (%)	Particle Size: Gravel (%)	% Sand (0.125mm - 0.063mm) (%)	% Sand (0.25mm - 0.125mm) (%)	% Sand (0.50mm - 0.25mm) (%)	% Sand (1.00mm - 0.50mm) (%)	% Sand (2.00mm - 1.00mm) (%)	% Silt (0.0312mm - 0.004mm) (%)	% Silt (0.063mm - 0.0312mm) (%)	Clay (%)	Stong Acid Leachable - Total Metals: Antimony (µg/g)	Arsenic (µg/g)	Barium (µg/g)	Beryllium (µg/g)	Cadmium (µg/g)	Chromium (µg/g)	Cobalt (µg/g)	Copper (µg/g)	Lead (µg/g)	Lithium (µg/g)	Manganese (µg/g)	Mercury (µg/g)	Molybdenum (µg/g)	Nickel (µg/g)	Selenium (µg/g)	Silver (µg/g)	Strontium (µg/g)	Tin (µg/g)	Uranium (µg/g)	Vanadium (µg/g)	Zinc (µg/g)

Associated ALS files: L1518225, L1519001, L1520490, L1522556, L1540219.
All terms defined within the body of SNC-Lavalin's report.
< Denotes concentration less than indicated detection limit or RPD less than indicated value.
- Denotes analysis not conducted.
n/a Denotes no applicable standard.
RPD Denotes relative percent difference.
* RPDs are not normally calculated where one or more concentrations are less than five times MDL.

BOLD Concentration greater than CSR Urban Park Land Use (PL) standard.

[a] The site-specific factors used for determining the matrix standards for this site include: intake of contaminated soil, groundwater used for drinking water, toxicity to soil invertebrates and plants, and groundwater flow to surface water used by freshwater aquatic life (whichever is most stringent).
[b] Standard varies with pH.

TABLE 1 (cont'd): Summary of Analytical Results for Physical Parameters, Particle Size and Total Metals in Soil

Sample Location	Sample ID	Sample Type	Sample Date (yyyy mm dd)	Depth Interval (m)	Miscellaneous Parameters: pH (pH)	Total Organic Carbon (%)	Total Inorganic Carbon (%)	Inorganic Carbon (as CACO3 Equiv) (%)	Moisture (%)	Particle Size: Gravel (%)	% Sand (0.125mm - 0.063mm) (%)	% Sand (0.25mm - 0.125mm) (%)	% Sand (0.50mm - 0.25mm) (%)	% Sand (1.00mm - 0.50mm) (%)	% Sand (2.00mm - 1.00mm) (%)	% Silt (0.0312mm - 0.004mm) (%)	% Silt (0.063mm - 0.0312mm) (%)	Clay (%)	Stong Acid Leachable - Total Metals: Antimony (µg/g)	Arsenic (µg/g)	Barium (µg/g)	Beryllium (µg/g)	Cadmium (µg/g)	Chromium (µg/g)	Cobalt (µg/g)	Copper (µg/g)	Lead (µg/g)	Lithium (µg/g)	Manganese (µg/g)	Mercury (µg/g)	Molybdenum (µg/g)	Nickel (µg/g)	Selenium (µg/g)	Silver (µg/g)	Strontium (µg/g)	Tin (µg/g)	Uranium (µg/g)	Vanadium (µg/g)	Zinc (µg/g)

Associated ALS files: L1518225, L1519001, L1520490, L1522556, L1540219.
All terms defined within the body of SNC-Lavalin's report.
< Denotes concentration less than indicated detection limit or RPD less than indicated value.
- Denotes analysis not conducted.
n/a Denotes no applicable standard.
RPD Denotes relative percent difference.
* RPDs are not normally calculated where one or more concentrations are less than five times MDL.

BOLD Concentration greater than CSR Urban Park Land Use (PL) standard.

[a] The site-specific factors used for determining the matrix standards for this site include: intake of contaminated soil, groundwater used for drinking water, toxicity to soil invertebrates and plants, and groundwater flow to surface water used by freshwater aquatic life (whichever is most stringent).
[b] Standard varies with pH.

TABLE 2: Summary of Soil Analytical Results for Nutrients and Salinity in Soil

All terms defined within the body of SNC-Lavalin's report.

< Denotes concentration less than indicated detection limit or RPD less than indicated value.

\- Denotes analysis not conducted.

n/a Denotes no applicable standard.

RPD Denotes relative percent difference.

* RPDs are not normally calculated where one or more concentrations are less than five times MDL.

BOLD Concentration greater than CSR Urban Park Land Use (PL) standard.

[a] The site-specific factors used for determining the matrix standards for this site include: intake of contaminated soil, groundwater used for drinking water, toxicity to soil invertebrates and plants, and groundwater flow to surface water used by freshwater aquatic life (whichever is most stringent).

[b] Values of less than method detection limit (0.5 meq/100g) were converted 0.25 meq/100g for estimating ESP.

TABLE 2 (Cont'd): Summary of Soil Analytical Results for Nutrients and Salinity in Soil

					Nutrients									Soil Salinity

All terms defined within the body of SNC-Lavalin's report.

< Denotes concentration less than indicated detection limit or RPD less than indicated value.

\- Denotes analysis not conducted.

n/a Denotes no applicable standard.

RPD Denotes relative percent difference.

* RPDs are not normally calculated where one or more concentrations are less than five times MDL.

BOLD Concentration greater than CSR Urban Park Land Use (PL) standard.

[a] The site-specific factors used for determining the matrix standards for this site include: intake of contaminated soil, groundwater used for drinking water, toxicity to soil invertebrates and plants, and groundwater flow to surface water used by freshwater aquatic life (whichever is most stringent).

[b] Values of less than method detection limit (0.5 meq/100g) were converted 0.25 meq/100g for estimating ESP.

All terms defined within the body of SNC-Lavalin's report.

< Denotes concentration less than indicated detection limit or RPD less than indicated value.

- Denotes analysis not conducted.

n/a Denotes no applicable standard.

RPD Denotes relative percent difference.

* RPDs are not normally calculated where one or more concentrations are less than five times MDL.

BOLD Concentration greater than CSR Urban Park Land Use (PL) standard.

[a] The site-specific factors used for determining the matrix standards for this site include: intake of contaminated soil, groundwater used for drinking water, toxicity to soil invertebrates and plants, and groundwater flow to surface water used by freshwater aquatic life (whichever is most stringent).

Table 4: Bulk Density Soil Log and Sample Results

Sample ID	Sample Date (yyyy mm dd)	Sample Type[a]	Description	Bulk Density (Mg/m^3)	Coordinates North (m)	Coordinates East (m)	Tailings Overburden Depth (m)	Sample Depth (m)
Hazeltine Creek								
ST01-01-BD-141001	2014 10 01	T	SILT (Tailings), sandy, fine grained, trace clay, grey, soft, low plasticity, wet	1.66	5817454	601636	-	0.0 - 0.15
ST01-02-BD-141001	2014 10 01	N (Till)	SILT (Till), sandy, fine to medium grained, trace gravel, brown, firm, no plasticity, damp	1.52	5817392	601726	0.05	0.05 - 0.20
ST02-01-BD-140930	2014 09 30	T	SAND (Tailings), some silt, grey, loose, damp	1.51	5817218	601122	-	0.0 - 0.15
ST02-02-BD-140930	2014 09 30	N (Lacustrine)	CLAY (Lacustrine), silty, trace fine grained sand, grey, soft, medium plasticity, moist	1.61	5817223	601092	0.00	0.0 - 0.15
ST03-01-BD-141001	2014 10 01	B	SILT (Till), sandy, fine grained, trace subrounded gravel, brown, soft, damp, low plasticity, roots/rootlets	1.04	5817280	600647	-	0.0 - 0.15
ST03-02-BD-141001	2014 10 01	N (Lacustrine)	CLAY (Lacustrine), silty, trace to some gravel, occasional cobbles, grey, stiff, medium plasticity, moist	2.00	5817303	600629	0.03	0.03 - 0.18
ST03-03-BD-141001	2014 10 01	T	SAND (Tailings), fine to medium grained, reddish brown with grey lenses, trace silt, loose, wet	1.38	5817308	600651	-	0.0 - 0.15
ST08-01-BD-141001	2014 10 01	B	SILT (Till), some fine to medium grained sand, trace clay, trace gravel, trace cobbles, light brown, firm, low plasticity, dry, roots/rootlets	1.26	5817321	598901	-	0 to 0.16
ST08-02-BD-141001	2014 10 01	T	SAND (Tailings), fine grained, some silt, grey, loose, wet to moist	1.67	5817276	598888	-	0 to 0.13
ST08-03-BD-141001	2014 10 01	N (Till)	SAND (Native), medium to coarse grained, some silt, some fine subrounded gravel, brown, loose, damp	1.86	5817280	598881	0.00	0.0 - 0.15
ST08-04-BD-141001	2014 10 01	N (Lacustrine)	SILT (Lacustrine), clayey, trace fine grained sand, grey, very stiff, damp	1.69	5817277	598786	0.00	0.0 - 0.12
ST11-01-BD-140930	2014 09 30	N (Till)	SILT (Till), sandy, fine to coarse grained, trace to some clay, some gravel, grey brown, firm, low plasticity, damp	1.82	5818118	597603	0.01	0.01 - 0.16
ST11-02-BD-140930	2014 09 30	T	SAND (Tailings), some silt, grey, loose, damp	1.59	5818109	597621	-	0.0 - 0.14
ST13-01-BD-140930	2014 09 30	N (Till)	SAND (Till), fine to medium grained, some silt, trace subrounded gravel, medium dense to dense, brown, damp, roots/rootlets	1.44	5819004	597036	0.03	0.03 - 0.18
ST13-02-BD-140930	2014 09 30	T	SAND (Tailings), fine to medium grained, trace silt, loose, moist	1.39	5818996	597021	-	0.0 - 0.15
ST14-01-BD-140930	2014 09 30	B	SILT (Till), some fine to medium grained sand, trace clay, frequent gravel, light brown, firm, no plasticity, dry, roots/rootlets	0.85	5819251	596545	-	0.0 - 0.14
ST15-01-BD-141002	2014 10 02	N (Till)	SAND (Till), fine to medium grained, silty, trace gravel, trace clay, reddish brown, dense, damp	1.90	5819982	595945	0.03	0.03 - 0.18
ST15-02-BD-141002	2014 10 02	T	SAND (Tailings), fine to medium grained, trace to some silt, grey, loose, damp to moist	1.52	5819985	595942	-	0.0 - 0.15
ST16-01-BD-141002	2014 10 02	T	SAND (Tailings), fine to medium grained, some silt, grey, loose, wet	1.60	5820124	595802	-	0.0 - 0.15
ST16-02-BD-141002	2014 10 02	B	SILT (Native), some fine grained sand, some gravel, dark brown to grey, firm, low plasticity, moist, roots/rootlets	0.90	5819959	595605	-	0.0 - 0.15
ST17-01-BD-141002	2014 10 02	T	SILT and CLAY (Tailings), some fine grained sand, grey, soft, medium plasticity, moist	1.54	5820221	595486	-	0 - 0.15
OBS02-01	2014 09 30	N	GRAVEL and COBBLES (Native), coarse, some sand, trace silt, grey, medium dense. No sample collected due to soil having estimated coarse fragment content > 50% (v/v).	-	5817222	601133	-	-
OBS03-01	2014 10 01	N	GRAVEL and COBBLES (Native) Coarse material across much of area upstream of new bridge location. No sample collected due to soil having estimated coarse fragment content > 50% (v/v).	-	5817297	600671	-	-
OBS08-01	2014 10 01	N	GRAVEL and COBBLES (Native), coarse, sandy, fine to medium grained, trace silt, grey brown, dense. No sample collected due to soil having estimated coarse fragment content > 50% (v/v).	-	5817272	598902	-	-
OBS13-01	2014 09 30	T	SAND (Tailings), fine to medium grained, trace to some silt, grey, loose, wet. No sample collected due to saturated and sloughing.	-	5818996	597015	-	-
OBS13-02	2014 09 30	D	SILT (Disturbed), some fine to medium grained sand, trace to some clay, light brown. Sample not collected given disturbed appearance and not being considered representative of transect conditions. Refer to Sample ST13-02-01-BD for description of till unit.	-	5819084	596930	-	-
OBS16-01	2014 10 02	N	SILT (Till), gravelly, frequent cobbles, brown, dense, damp. No sample collected due to soil having estimated coarse fragment content > 50% (v/v).	-	5820069	595840	-	-
OBS16-02	2014 10 02	F	BOULDERS and COBBLES (Fill / Suspect Dam Materials), coarse, angular, gravelly, variable colour. No sample collected due to soil having estimated coarse fragment content > 50% (v/v).	-	5820243	595782	-	-
OBS17-01	2014 10 02	T	SILT and CLAY (Tailings), some fine grained sand, grey, very soft, medium plasticity, moist to wet. No sample collected as soil appeared similar to that sampled at ST17-01-BD.	-	5820501	595346	-	-

Soil Classification Code Description from *Soils of the Horsefly Area* by T.M. Lord (1984)

Code	Name	Material	Surface Expression	Water Regime of Dominant Soil	Classification of Dominate Soil
CC-SW/2	Catfish Creek – Spakwaniko	Moderately decomposed sedge fen peat and loamy morainal and colluvial materials	Level, undulating	Aquic, very poorly drained, moderately pervious	Typical Mesisol
LZ-D/3-4	Lanezi – Deserters	Loamy morainal, and sandy and loamy morainal and colluvial materials	Inclined, ridged, blanket and veneer	Perhumid to humid, moderately well drained, moderately pervious	Luvisolic-Humo-Ferric Podzol
MF-LZ	Moffat Lakes – Lanezi	Gravelly, sandy and loamy skeletal and loamy morainal materials	Undulating, rolling	Humid to subhumid, well drained, moderately to rapidly pervious	Eluviated Dystric Brunisol

APPENDIX II

Laboratory Analytical Methods

[illegible]

ALS Test Code	Matrix	Test Description	Method Reference**	Method Reference
HG-200.2-CVAF-VA	Soil	Soil samples are digested with nitric and hydrochloric acids, followed by analysis by CVAFS.	EPA 200.2/1631E (mod)	U.S. Environmental Protection Agency
MET-200.2-CCMS-VA	Soil	Soil samples are digested with nitric and hydrochloric acids, followed by analysis by CRC ICPMS.	EPA 200.2/6020A (mod)	U.S. Environmental Protection Agency
EPH-TUMB-FID-VA	Soil	EPH in Solids by Tumbler and GCFID	BC MOE EPH GCFID	U.S. Environmental Protection Agency
VOC-M2-HSMS-VA	Soil	The soil methanol extract is added to water and reagents, then heated in a sealed vial to equilibrium. The headspace from the vial is transferred into a gas chromatograph. Target compound concentrations are measured using mass spectrometry detection.	EPA8260B, 5021, BC MELP	U.S. Environmental Protection Agency BC Ministry of Environment, Lands, and Parks
PH-1:2-VA	Soil	This analysis is carried out in accordance with procedures described in the pH, Electrometric in Soil and Sediment method - Section B Physical/Inorganic and Misc. Constituents, BC Environmental Laboratory Manual 2007. The procedure involves mixing the dried (at <60°C) and sieved (No. 10 / 2mm) sample with deionized/distilled water at a 1:2 ratio of sediment to water. The pH of the solution is then measured using a standard pH probe.	BC WLAP METHOD: PH, ELECTROMETRIC, SOIL	BC Ministry of Water, Land and Air Protection
ALK-PASTE-VA	Soil	A soil extract produced by the saturated paste extraction procedure is analyzed for alkalinity by methyl orange colourimetry.	Carter-CSSS / EPA 310.2 (modified)	Canadian Society of Soil Science
CL-PASTE-COLOR-VA	Soil	A soil extract produced by the saturated paste extraction procedure is analyzed for chloride by ferricyanide colourimetry.	Carter-CSSS / APHA 4500-Cl E (modified)	Canadian Society of Soil Science
EC-PASTE-VA	Soil	A soil extract produced by the saturated paste extraction procedure is analyzed by conductivity meter.	Carter-CSSS / APHA 2510B	Canadian Society of Soil Science

MET-PASTE-ICP-VA	Soil	A soil extract produced by the saturated paste extraction procedure is analyzed for Sodium, Calcium, and Magnesium by ICPOES as per "Soil Sampling and Methods of Analysis" by M. Carter.	Carter-CSSS / EPA 6010B (modified)	Canadian Society of Soil Science
NO3-PASTE-IC-VA	Soil	A soil extract produced by the saturated paste extraction procedure is analyzed for nitrate (as N) by Ion Chromatography with conductivity or UV detection.	Carter-CSSS / EPA 300.1 (modified)	Canadian Society of Soil Science
SAR-PASTE-CALC-VA	Soil	A soil extract produced by the saturated paste extraction procedure is analyzed for Sodium, Calcium, and Magnesium by ICPOES. Sodium Adsorption Ratio (SAR) is calculated as per "Soil Sampling and Methods of Analysis" by M. Carter.	Calculation	n/a
SAT-PCNT-VA	Soil	Saturation Percentage (SP) is the total volume of water present in a saturated paste (in mL) divided by the dry weight of the sample (in grams), expressed as a percentage, as described in "Soil Sampling and Methods of Analysis" by M. Carter.	Carter-CSSS	Canadian Society of Soil Science
SO4-PASTE-IC-VA	Soil	A soil extract produced by the saturated paste extraction procedure is analyzed for sulfate by Ion Chromatography with conductivity detection.	Carter-CSSS / EPA 300.1 (modified)	Canadian Society of Soil Science
TGR2-CALC-VA	Soil	Theoretical Gypsum Requirement is an estimate of the gypsum amendment required to remediate brine-contaminated or sodic soils, and is provided in units of tonnes per hectare (t/ha) for a treatment depth of 15cm. TGR(brine), intended for brine-contaminated soils, is calculated using Method A from "A Comparison of Methods for Gypsum Requirement of Brine-Contaminated Soils", by J. Ashworth (Cdn J. of Soil Science, 1999), available at www.alsglobal.com. TGR(sodic), intended for naturally sodic soils, uses the Oster and Frenkel method (Method B) from the same paper. Reported TGR values are capped	J. Ashworth et al (1999) Canadian Journal of Soil Science 79	

		at 50 t/ha, considered the maximum practical gypsum amendment. To convert TGR from t/ha to tons/acre, multiply by 0.446. To determine a TGR value for an alternate treatment depth, multiply by [desired treatment depth (cm) / 15 cm].		
LEPH/HEPH-CALC-VA		Light and Heavy Extractable Petroleum Hydrocarbons in Solids. These results are determined according to the British Columbia Ministry of Environment, Lands, and Parks Analytical Method for Contaminated Sites "Calculation of Light and Heavy Extractable Petroleum Hydrocarbons in Solids or Water". According to this method, LEPH and HEPH are calculated by subtracting selected Polycyclic Aromatic Hydrocarbon results from Extractable Petroleum Hydrocarbon results. To calculate LEPH, the individual results for Naphthalene and Phenanthrene are subtracted from EPH(C10-19). To calculate HEPH, the individual results for Benz(a)anthracene, Benzo(b)fluoranthene, Benzo(k)fluoranthene, Benzo(a)pyrene, Dibenz(a,h)anthracene, Indeno(1,2,3-c,d)pyrene, and Pyrene are subtracted from EPH(C19-32). Analysis of Extractable Petroleum Hydrocarbons adheres to all prescribed elements of the BCMELP method "Extractable Petroleum Hydrocarbons in Solids by GC/FID" (Version 2.1, July 20, 1999).	BC MOE LABORATORY MANUAL (2005)	
PAH-TMB-H/A-MS-VA		This analysis is carried out using procedures adapted from "Test Methods for Evaluating Solid Waste" SW-846, Methods 3570 & 8270, published by the United States Environmental Protection Agency (EPA). The procedure uses a mechanical shaking technique to extract a subsample of the sediment/soil with a 1:1 mixture of hexane and acetone. The extract is then solvent exchanged	EPA 3570/8270	U.S. Environmental Protection Agency

		to toluene. The final extract is analysed by capillary column gas chromatography with mass spectrometric detection (GC/MS). Surrogate recoveries may not be reported in cases where interferences from the sample matrix prevent accurate quantitation. Because the two isomers cannot be readily chromatographically separated, benzo(j)fluoranthene is reported as part of the benzo(b)fluoranthene parameter.

After cooling, the resulting solution is diluted to with deionized water, mixed and analyzed by inductively coupled plasma-atomic emission spectrometry. Following this analysis, the results are reviewed for high concentrations of bismuth, mercury, molybdenum, silver and tungsten and diluted accordingly. Samples are	Aqua Regia ICPMS	

APPENDIX III

Quality Assurance/Quality Control

APPENDIX III: QUALITY ASSURANCE/QUALITY CONTROL

For the SQIA, SNC-Lavalin and ALS implemented Quality Assurance and Quality Control (QA/QC) procedures as described and discussed below.

SNC-Lavalin QA/QC Methodology

SNC-Lavalin personnel followed internally established QA/QC protocols for field activities and verified QA/QC programs implemented by laboratories. This program included field, office and duplicate procedures. A list of components included in field, office and duplicate procedures are listed below:

- Senior supervision of field staff.
- Use of in house trained personnel.
- Implementation of SNC-Lavalin preferred operating procedures (POPs).
- Written field instructions.
- Documentation of all field activities:
  - Samples will be collected in a manner appropriate for the prevention of cross-contamination and other field sampling errors. Samples will be collected using an appropriate contaminant-free utensil and placed in contaminant-free containers specifically designed for such use and appropriate to the subsequent analyses.
- Chain-of-custody documentation for sample submission:
  - Use of an appropriate coding system for submitting samples to the analytical laboratory to ensure that information concerning location or expected concentration is unavailable to the analyst(s). A chain-of-custody form will be established to trace the movement and handling of samples from the field to their final destination.
- Use of a Canadian Association of Laboratory Accreditation (CALA) accredited laboratory.
- Adherence to laboratory sampling and analysis protocols (e.g., hold times, sample containers, preservatives, detection limits, approved methodology).
- Procedures to confirmation accurate transcription of laboratory data into tables.
- Review of laboratory QC performance (standards, spike recoveries etc.) to confirm results are within acceptable limits.
- At least one analytical (lab) duplicate for each batch of analyses.
- Results of the laboratory's internal checks will be included in the analytical report.
- Decontamination of sampling (trowels, mixing bowls) between sample locations.

- Use of an appropriate coding system for submitting samples to analytical laboratories to ensure that information concerning sample location or expected concentrations was unavailable; and
- Procedures to confirm the quality of field screening data by comparison of field data to laboratory analytical results;
- Development and implementation of a QA/QC flow chart to ensure all staff is aware of requirements and roles (see flow chart below).

Duplicate Samples

- Duplicate samples were collected in order to determine sampling precision. Blind field duplicates were submitted to the laboratory at an approximate frequency of 1 per 10 samples analyzed, as summarized in Table 1 below.

Table 1: Summary of Soil Quality Analysis including Duplicates

Parameter	Number of Samples Analyzed			
	Tailings	Within channel native	Background	Duplicates
Total Metals + pH	71	17	23	11
Nutrients	27	14	19	3*
Salinity	27	14	18	3*
Mine Processing Reagents	7	1	0	1
Grain (Particle) Size	19	13	0	3
Bulk Density	9	8	4	0

Note:

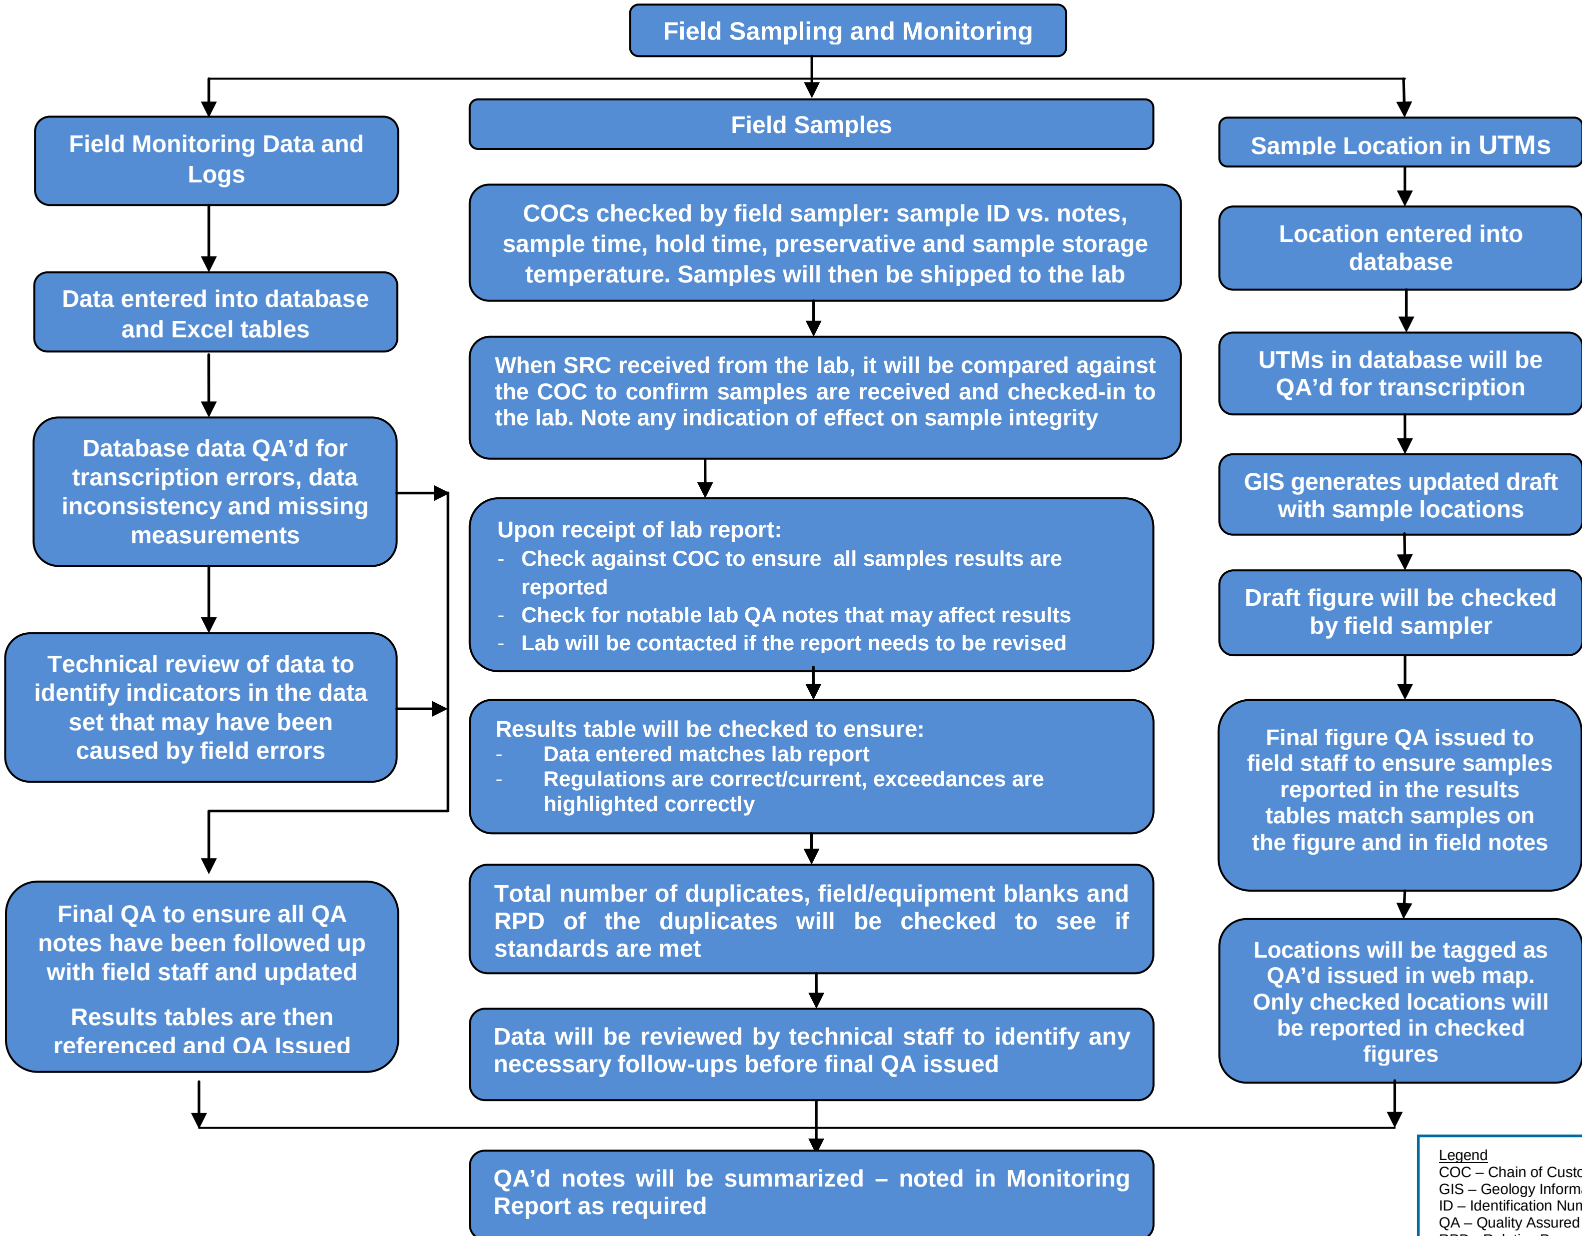
***** Seven duplicates were analyzed for parameters, however three samples had both the sample and the corresponding duplicate sample analyzed and four samples had the duplicate sample analyzed but not the corresponding sample analyzed.

- Analytical precision was evaluated by calculating the relative percent difference (RPD) between the results of each sample and its associated duplicate. The RPD is the absolute value of the difference between the two results divided by the average of the two results and is reported as a percentage, demonstrated as follows:

$$RPD = abs\ [(C_{sample} - C_{duplicate})/(C_{sample} + C_{duplicate})/2]*100$$

- Due to the sample heterogeneity, attributed primarily to site stratigraphy, SNC-Lavalin's select target range for RPDs was 60% for metals, Volatile Organic Carbon (VOC) and other organics including Light and Heavy Extractable Petroleum Hydrocarbons (LEPH/HEPH) and Glycol parameters in soil; and was 75% for Polycyclic Aromatic Hydrocarbons (PAH).

- RPD values greater than these values indicated that the variability was outside of SNC-Lavalin’s target range. When the analytical result of the original or duplicate sample was less than five times the laboratory detection limit, RPDs were not considered meaningful due to a relative increase in analytical variability at or near detection limits. Therefore, RPDs in such scenarios were not calculated.



Legend
COC – Chain of Custody
GIS – Geology Information System
ID – Identification Number
QA – Quality Assured
RPD - Relative Percent Difference
SRC – Sample Receive Confirmation
UTM - Universal Transverse Mercator

Additional QA/QC Notes

- Duplicate samples ST06-01-03 (duplicate of ST06-01-02), ST15-01-03 (duplicate of ST15-01-02), and ST18-05-02 (duplicate of ST18-05-01) along with their corresponding samples were analyzed for total metals, however only the duplicate samples were analyzed for nutrients and salinity parameters.
- Duplicate samples ST02-02-03 (duplicate of ST02-02-01) and ST14-02-02 (duplicate of ST14-02-01) along with their corresponding samples, were analyzed for total metals, but only the corresponding samples (not duplicates) were analyzed for particle size and/or nutrients and salinity.
- Sample ST18-05-02 only had total inorganic carbon (not total carbon) analyzed, and thus total organic carbon could not be calculated.

Laboratory QA/QC Procedures

In addition to QA/QC procedures implemented by SNC-Lavalin, the laboratory (ALS) also implements quality control. ALS's quality control included: Matrix Spikes, Spiked Blanks, Method Blanks, Duplicate Samples and Quality Control Standards. The definition of each of these is included below.

- **Matrix Spike:** a sample to which a known amount of the analyte of interest has been added. The blank spike sample is then carried through the sample analysis and preparation steps. Matrix spike samples are used to evaluate the accuracy of the method.
- **Spiked Blank:** a sample prepared by adding a known amount of analyte, usually from a secondary source, to a specified amount of sample (matrix). The blank spike sample is then carried through the sample analysis and preparation steps. Blank spike samples provide a measure of the analytical method's accuracy.
- **Method Blank:** a sample that is intended to contain none of the analytes of interest. A blank is used to detect contamination during sample handling preparation and/or analysis.
- **Duplicate Sample:** In addition to blind field duplicates collected by SNC-Lavalin, the laboratory also has a duplicate procedure which includes preparation and analysis of a replicate aliquot of a sample. Duplicates are analyzed to evaluate the variance in the measurement. The RPD for duplicate samples is reported.
- **Quality Control (QC) Standard:** a blank matrix to which a known amount of analyte has been added. This procedure is used to evaluate analyte recovery.

Laboratory QA/QC Results

The detailed results of the laboratory QA/QC are included in analytical reports contained in Appendix V.

Summary

The results of the QA/QC assessment were considered to be acceptable. Although two RPD results were in exceedance of SNC-Lavalin target value of 60% or 75%, the RPD exceedance did not affect the interpretation of results.

PLAIN LANGUAGE SUMMARY

This report, prepared by Minnow Environmental Inc., provides an interim assessment of the impact of the August 4, 2014 Mount Polley tailings dam failure on receiving environment sediment quality. The failure resulted in the discharge of tailings and water into Polley Lake, Hazeltine Creek and Quesnel Lake.

The two key factors in the assessment of failure-related effects on sediment quality are: 1) changes to physical conditions of the sediment, and 2) changes in chemical composition of the sediment. Both of these can affect the capacity of sediment to support sediment dwelling organisms.

Several tools were used to assess the impact of the failure on sediment quality:

1. Measures and observations of sediment physical properties including sediment colour, texture, particle size composition, and organic carbon content;

2. Measurements of chemical content of sediment (including metals that were elevated in tailings);

3. Testing the toxicity of the sediment to indicator invertebrate species under laboratory conditions; and

4. Direct measurement of diversity and abundance of organisms in the benthic invertebrate community.

Analyses were conducted on sediment collected from Hazeltine Creek, Polley Lake, and Quesnel Lake. Sediment was not collected from the erosional Quesnel River, but this area was evaluated on the basis of the benthic invertebrate community and supporting water chemistry. Several locations were sampled in each of these water bodies, and multiple samples were collected at each location to characterize small-scale variations. Impact was characterized in comparison to sediment quality guidelines and reference (including pre-failure) sediment chemistry, the latter of which indicated naturally elevated concentrations of a number of metals prior to the dam failure. As expected, locations closest to the dam failure (or within the debris field downstream) were associated with the greatest disturbance in sediment physical condition, compared to those located further down Quesnel Lake. Many of these locations also exhibited elevated concentrations of sediment-associated metals, particularly copper.

Sediments in the failure-affected aquatic environments were associated with concentrations of copper that consistently exceeded provincial sediment quality guidelines

and that were several times higher than reference concentrations; these sediments also exhibited low total organic carbon content compared to reference sediments. Several studies conducted in collaboration with the geochemical assessment indicated low potential for bioavailability of metals to sediment-dwelling organisms under field conditions. Selective chemical extractions indicated that most metals were significantly liberated only in the strongest acid digest, meaning that they cannot be mobilized under natural conditions in the field. Copper was liberated in less aggressive extractions, but separate geochemical evaluation (SRK 2015) indicated limited copper mobility. These geochemical findings indicate that, although concentrations of several metals in sediment exceeded provincial guidelines, the copper and other associated metals may not be harmful.

Standard toxicity test organisms were evaluated under laboratory conditions to determine if sediment-dwelling organisms could survive and grow normally. In several samples, these organisms did not survive or grow as successfully as those exposed to reference sediment. The toxicity test results were difficult to interpret because the physical composition of tailings-influenced sediments differed from natural sediment. For example, organic carbon in the sediment, which is a food source for the test organisms, was very low in many samples (approximately 0.5% or lower at the most impacted locations). When poor growth or survival was observed, samples also contained much less organic carbon than recommended for normal performance of the tests. It is therefore possible that toxicity in some samples was due to food limitations, chemical influence, or both factors acting together. However, the study also provided indications of normal growth and survival in sediments that were collected distant from the areas of greatest tailings influence (i.e., Quesnel Lake locations distant from Hazeltine Creek).

Analysis of sediment-dwelling benthic invertebrate communities indicated fewer invertebrates and lower diversity in Hazeltine Creek, Polley Lake, and areas of Quesnel Lake that were influenced by the dam failure. This is expected because the dam failure and erosion of Hazeltine Creek would have resulted in scouring of the natural sediment, plus deposition of foreign materials on the sediment surface. The degree of physical and chemical impact was not constant across the study area. For example, invertebrate diversity and abundance in the samples from the shallow parts of Quesnel Lake more distant from Hazeltine Creek and in the Quesnel River showed normal diversity and abundance, indicating that benthic invertebrate communities in these locations were not impacted by the dam failure.

The results of this interim assessment indicate that there is strong evidence of an impact to sediments within Hazeltine Creek and within portions of Polley Lake and Quesnel Lake. The degree of physical, chemical and biological impact is consistent with the degree of tailings influence, which varies by location and type of habitat. Although both physical and chemical factors may be responsible for the observed biological effects, the data suggest that the physical impacts are the greater influence on the sediment-dwelling organisms for two reasons: 1) sediment geochemistry indicates that metals have low availability for uptake by sediment-dwelling invertebrates, and 2) the magnitude of responses to the benthic community are larger than would be expected from the sediment toxicity test results. Because the assessment was conducted within a few months of the tailings dam failure, benthic organisms would not have had sufficient time to re-establish following the disturbances related to the failure.

Hazeltine Creek is currently being restored and tailings have been removed from the creek bed. Benthic invertebrate succession is occurring naturally from the surrounding environment. Follow-up sampling and testing will be conducted in 2015 to further characterize sediment conditions and to monitor benthic invertebrate community abundance and diversity succession.

1.0 INTRODUCTION

1.1 Site Description and Background

The Mount Polley Mining Corporation (MPMC) operates the Mount Polley copper-gold mine located approximately 9 kilometers southwest of the community of Likely, British Columbia and 56 kilometres north-east of the city of Williams Lake, British Columbia (Figure 1.1). Mining at Mount Polley was active from 1997 to 2001 and from 2005 to August 4th 2014, and has included the mining of six open pits (Figure 1.1) and one underground mine accessed through the Wight Pit. The Mount Polley Mine site also includes a crusher and mill (concentrator), waste rock disposal sites, a Tailings Storage Facility (TSF), seepage collection ponds, a surface water collection system, a settling pond, and access roads (Figure 1.1).

Early on the morning of August 4th 2014, the Mount Polley TSF dam failed and released an estimated 25.0 million cubic metres of water and tailings. The material flowed in a northeast direction to Polley Lake and in a southeast direction along Hazeltine Creek and into Quesnel Lake.

1.2 Objective

The objective of this sediment quality impact characterization is to characterize the impact of the tailings dam failure on receiving environment sediment quality (including spatial extent and magnitude). This includes the characterization of sediment geochemistry as it pertains to the potential mobility and bioavailability of sediment-associated metals and metalloids. It also includes application of an enhanced sediment quality triad (SQT) approach (concurrent sediment chemistry, sediment geochemistry, toxicity, and benthic invertebrate community monitoring) to evaluate potential effects of failure-impacted sediment to aquatic life. Sediment geochemistry was also evaluated separately in consideration of all available tailings and receiving environment geochemical data (SRK 2015), and associated findings are referenced in this report.

1.3 Report Overview

This report is presented in ten sections, the first of which is this introduction (Section 1.0). Section 2.0 provides an overview of the approach and study design for the sediment quality impact assessment. Section 3.0 provides a review of historical data used in the impact assessment. Section 4.0 provides the methods used in the collection of sediment quality data and in impact assessment. Sections 5.0 through 9.0 provide the results and assessment of data collected in Hazeltine Creek, Polley Lake, Quesnel Lake littoral,

Quesnel Lake profundal and Quesnel River (Figure 1.2), respectively. Each of these sections begins with basic sediment quality (total concentrations) and is then augmented with the results of geochemical analyses undertaken to characterize the mobility of sediment-associated metals (including those undertaken by SRK [2015]). Results of sediment toxicity testing and benthic invertebrate community characterizations are then presented, both of which are considered in light of the chemical/geochemical characterizations. Each of sections 5.0 to 9.0 concludes with an integrated evaluation of the findings using a weight of evidence approach (WEA) to characterize sediment quality impact. Section 10.0 provides a summary of findings, including integrated conclusions of impact through the areas discussed independently in Sections 5.0 to 9.0. All references cited throughout the report are provided in Section 11.0.

2.0 APPROACH

2.1 Overall Approach

As stated in Section 1.2, the general objective of the Sediment Quality Impact Characterization (SQIC) was to characterize the impact of the tailings dam failure on receiving environment sediment quality. For the purposes of this assessment, Hazeltine Creek was considered a receiving environment although it currently does not represent an aquatic habitat. Restoration work is underway for Hazeltine Creek and it is planned to be a restored aquatic habitat in the future. The SQIC included the collection of physical, chemical and biological data from August to October 2014.

The study area, as defined in discussions among MPMC and environmental regulatory agencies, extends from the Mount Polley Mine Tailings Storage Facility (TSF) to the University of Northern British Columbia Quesnel River Research Centre (QRCC; Figure 1.2). This study area includes the following affected water bodies:

- Polley Lake;
- Hazeltine Creek;
- Quesnel Lake; and
- the Quesnel River.

A number of sampling areas were identified within each waterbody in an experimental design that included areas potentially affected by the tailings dam failure (including a spatial gradient where possible) and suitable reference areas, all with replication within areas (generally five stations per area; Table 2.1; as described in detail in Section 4.0).

Within Polley Lake, Hazeltine Creek, Quesnel Lake and Bootjack Lake (which served as a reference for Polley Lake), the SQIC included (Table 2.1):

1. Sediment sampling to characterize sediment physical and chemical characteristics (including total metals in both <2.0 mm and <63 µm sediments). This study component serves to characterize the physical and chemical impact of the dam failure on receiving environment sediments.
2. Geochemical characterization of the sediments using selective chemical extraction, shake flask tests, sediment porewater chemistry, acid-base accounting and particle size fractionation. This study component serves to characterize the potential mobility of sediment-associated metals.

● data collected in August to October 2014

○ data collected at a subset of areas

[1] the majority of areas were characterized at five stations per area (see Section 4.0 for additional detail)

3. Sediment core collection for the characterization of vertical patterns of sediment chemistry and sediment porewater chemistry. This study component serves to characterize the potential for the mobilization of metals from sediment to overlying water.

4. Sediment toxicity testing using two test organisms – the freshwater/brackish water amphipod *Hyalella azteca* and the freshwater midge *Chironomus dilutus.* This study component serves to characterize the influence of failure-impacted sediments on the survival and growth of toxicity test organisms.

5. Benthic invertebrate community characterization using a number of community-level endpoints (density, taxon richness, diversity, evenness, community composition). This study component serves to characterize the influence of failure-impacted sediments on in-situ benthic invertebrate communities using sensitive endpoints that account for community-level interactions.

Within the Quesnel River, which is erosional and does not support sediment accumulation, the impact characterization included (Table 2.1):

1. Benthic invertebrate community characterization using a number of community-level endpoints (density, taxon richness, diversity, evenness, community composition). This study component serves to characterize the bioavailability of metals and the potential influence of the event on in-situ benthic invertebrate communities of the Quesnel River using sensitive endpoints that account for community-level interactions.

2. Benthic invertebrate tissue quality, including composite samples of the whole benthic invertebrate community and composite samples of one of the most common taxonomic groups (Perlidae, insects of the family Plecoptera [stoneflies], often referred to as common stoneflies). This study component serves to characterize the potential influence of the event on tissue chemistry of in-situ benthic invertebrates of the Quesnel River.

The data collected are used to provide a characterization of the physical and chemical impacts of the dam failure on sediment quality, as well as a characterization of the potential biological effects. To focus the analysis, the sediment quality evaluation included the identification of specific analytes whose concentrations in the study areas were most impacted by the dam failure. As described in detail in Section 4.0, these analytes are identified as either Parameters of Interest (POIs), which are analytes that were impacted by the failure to concentrations of concern with respect to potential effects to aquatic life (i.e., relative to effect-based guidelines and reference or pre-failure concentrations), and Indicator Parameters (IPs), which are analytes that were clearly associated with the failure (i.e., were substantially elevated relative to reference or pre-failure concentrations), but which remain lower than effect-based guidelines or for which no effect-based guidelines have been developed.

The interpretation of spatial differences in sediment chemistry, of the geochemical data, and of relationships between chemistry and biological responses were based on the POIs and the IPs in order to focus the SQIC on substances that represent the greatest risk to aquatic biota or are potentially most representative of the influence of the tailings dam failure. For these substances, environmental mobility was characterized and linked to measured biological observations to interpret bioavailability, effect and cause. Evaluation of the POIs in this manner is required because concentration-based screening tools (e.g., Sediment Quality Guidelines for the protection of aquatic life; BCMoE 2015a, 2015b) are suited to identifying concentrations below which effects are unlikely, but have a poor track record of predicting in-situ effects, particularly in instances where background concentrations are elevated and where the geochemical characteristics of the sediment differ from those under which the guidelines were developed (e.g., Prairie and McKee 1994; Campbell and Tessier 1996; ICMM 2007; Luoma and Rainbow 2008). Overall, the approach provides a solid basis for the initial characterization of the impact of the MPMC tailings dam failure on sediment quality.

2.2 Impact Characterization

Impact characterization includes physical impact (where and how have sediment physical characteristics been affected by the dam failure), chemical impact (where and how have sediment chemical and geochemical characteristics been affected by the dam failure), and biological impact (where and how have sediment-associated aquatic invertebrates been affected by the dam failure). Characterization of the physical and chemical impact on sediment includes the delineation of the affected area accomplished using a combination of electronic imaging and chemical characterization. Chemical impact is characterized by defining the differences in sediment chemistry relative to the pre-existing chemical condition and/or an appropriate reference chemical condition. Biological impact characterization is based on a weight-of-evidence approach (e.g., Burton et al 2002; Weed 2005; Suter and Cormier 2011; Alexander et al. 2015), whereby the chemical data, geochemical data, and biological data (toxicity testing and benthic invertebrate community structure) are integrated to identify biological impact relative to the pre-existing condition and/or an appropriate reference condition. This approach includes an enhanced

Sediment Quality Triad (SQT; Chapman 1990), with the additional consideration of chemical techniques for the estimation of metal mobility/bioavailability.

3.0 REVIEW OF HISTORICAL DATA

3.1 Environmental Context

To provide an effective basis for sediment quality impact characterization (i.e., comparison of data collected in 2014 to historical data), the pre-event receiving (Polley Lake, Hazeltine Creek, and Quesnel Lake) and reference (Bootjack Lake) environments were characterized based on existing physical, chemical, and biological data. Specifically, the assessment of data collected in 2014 relies substantially on comparison to pre-failure and reference conditions, and it is therefore important to understand sediment quality prior to the dam failure, including natural elevations in sediment metal concentrations relative to guidelines typically used in sediment quality assessment. These waterbodies have been previously characterized to various extents by the mine and a recent description of the receiving environments (Minnow 2014a) was used as a starting point, augmented with relevant data obtained through the Quesnel River Research Center. Available physical, chemical, and biological information for these waterbodies was compiled, and an inventory of the information reviewed is provided in Table 3.1.

3.2 Hazeltine Creek

The sediment quality of Hazeltine Creek has been assessed as part of several studies, both during baseline for the Mount Polley Mine in 1995 and 1996 (HKP 1996; HKP 1997), as well as during mine operation (Beak 2000; Minnow 2009; Minnow 2011; Karimlou 2011; van Lipzig 2011; Minnow 2013b; Minnow 2013c). Both the upper and lower regions of the creek have been evaluated in these studies (Figure 3.1), covering the area from the outlet of Polley Lake into Hazeltine Creek to the outlet of Hazeltine Creek into Quesnel Lake (Figure 3.1).

The assessment of sediment quality completed during baseline studies included sampling stations in upper Hazeltine Creek (W7) and in lower Hazeltine Creek (W11) (Tables 3.2-3.3, Appendix Tables A.1-A.2). The results of this sediment quality monitoring should be tempered by consideration that Hazeltine Creek is primarily an erosional creek and that the results of this monitoring include some unusually high concentrations of metals reported in 1996 (HKP 1997) that were not observed in 1995 (HKP 1996) and have not been observed since. These elevated concentrations may have been due to some unusual collection methods employed in 1995 and 1996 (e.g., using a coffee can), and the fact that baseline metal analyses were conducted only on the <63 µm fraction (silt and clay). Nonetheless, when compared to the BC Sediment Quality Guideline threshold effect levels (TEL; BCMoE 2015a, 2015b) mean 1995 baseline metals concentrations

Table 3.1: Inventory of Physical, Chemical and Biological Data Sources for Hazeltine Creek, Polley Lake, Bootjack Lake, and Quesnel Lake.

Study	Report Year	Scope of Study	Reference
The Paleolimnology of Eight Sockeye Salmon Nursery Lakes in British Columbia, Canada	1980	Documenting historic changes in trophic state of lakes (including Quesnel Lake) by examining diatoms in sediment cores	Stockner and Costella 1980
Environmental and Socioeconomic Impact Assessment for the Mount Polley Project	1990	Pre-development environmental and socio-economic impact assessment of the Mount Polley Mine project	Imperial Metals 1990
Mount Polley Project - Environmental Baseline and Monitoring Report 1995	1996	Environmental baseline study documenting pre-development conditions of aquatic and terrestrial ecosystems	HKP 1996
Mount Polley Project - Environmental Baseline and Monitoring Report 1996	1997	Continuation of 1996 environmental baseline study documenting baseline aquatic and terrestrial conditions	HKP 1997
Mount Polley Biological Monitoring Program - 1999	2000	Documenting baseline aquatic biological conditions in the vicinity of the Mount Polley Mine and supporting chemical measurements in water and sediment	Beak 2000
Hazeltine Creek Habitat Characterization	2007	Documenting the baseline physical habitat characteristics and fish habitat features	Minnow 2007a
Hazeltine Creek Habitat Characterization of the Reach below the New Proposed Effluent Discharge Location	2007	Continuation of work for Minnow 2007a but below the new proposed effluent discharge location	Minnow 2007b
Analysis of Baseline Water Quality Data of Hazeltine Creek at Station W7	2007	Baseline water quality at Station W7	Minnow 2007c
Analysis of Historical Data for the Identification of Optimal Timing for Potential Toxicity Testing in Hazeltine Creek	2007	Using the Biotic Ligand Model to predict seasonal patterns of copper bioavailability in Hazeltine Creek	Minnow 2007d
Mount Polley Mine - Aquatic Environmental Characterization of Hazeltine Creek - 2007	2009	Document the physical, chemical and biological conditions that could be affected by proposed discharge to Hazeltine Creek in a pre-discharge Environmental Effects Monitoring (EEM) study using EEM protocols	Minnow 2009
Mount Polley Mine Technical Assessment Report for a Proposed Discharge of Mine Effluent	2009	Technical assessment of the potential environmental impact of proposed discharge to Hazeltine Creek	Mount Polley 2009
Mount Polley Mine - Evaluation of the Water Quality of Polley and Bootjack Lakes	2010	Existing water quality of Polley Lake and evaluation of the influence of the mine on the water quality of the lake	Minnow 2010
Mount Polley Mine Selenium Monitoring 2009/2010	2011	Selenium monitoring in sediment, periphyton, benthic invertebrates and fish	Minnow 2011
Effects of mining on fine sediment quality; a comparison with regional metal background concentrations	2011	Assessment of mining influence on sediment quality of creeks within the Quesnel River catchment, including 3 sites within Hazeltine Creek	Karimlou 2011
Effects of mining on the geochemistry of fine sediments in streams; a study in the Quesnel River catchment	2011	Investigation of mining influence on the geochemistry of creek sediments in the Quesnel River catchment, including 3 sites within Hazeltine Creek	van Lipzig 2011
Phosphorus in Polley Lake	2013	Review of phosphorus in Polley Lake, investigate source of phosphorus and implications of increased phosphorus in lake	Minnow 2013a
Mount Polley Mine Selenium Monitoring 2012	2013	Selenium monitoring in sediment, periphyton, benthic invertebrates and fish	Minnow 2013b
Mount Polley Mine Selenium Monitoring 2013 Update Report	2013	Selenium monitoring in sediment, periphyton, benthic invertebrates and fish	Minnow 2013c
Aquatic Environmental Description Report Mount Polley Mine Discharge of Treated Water to Polley Lake	2014	Review of physical, chemical, and biological characteristics of Polley Lake and Hazeltine Creek, in support of proposed discharge to Polley Lake	Minnow 2014a
Technical Assessment Report Mount Polley Mine Discharge of Treated Water to Polley Lake	2014	Technical assessment of the potential environmental effects associated with proposed discharge of treated effluent to Polley Lake	Minnow 2014b

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.
[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b) - TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.
[3] concentrations reported in 1995 and 1996 were for the silt and clay (<63 µm) fraction only.
[4] some unusually high sediment metal concentrations were reported for 1996 (HKP 1997) and are suspected errors.
[5] Particle fractions for these samples are as follow: gravel (>2mm), sand (2.0mm-0.050mm), silt (0.050mm-0.002mm), clay (<0.002mm).
[6] Summary statistics exclude data from 1996 (HKP 1997) due to suspected errors with this data.

(blue) indicates a mean concentration greater than the BCSQG TEL.
(orange) indicates a mean concentration greater than the BCSQG PEL.

Table 3.3: Sediment quality of lower Hazeltine Creek, 1995-2013 [1].

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.

[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b) - TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.

[3] concentrations reported in 1995 and 1996 were for the silt and clay (<63 µm) fraction only.

[4] some unusually high sediment metal concentrations were reported for 1996 (HKP 1997) and are suspected errors.

[5] Particle fractions for these samples are as follow: gravel (>2mm), sand (2.0mm-0.050mm), silt (0.050mm-0.002mm), clay (<0.002mm).

[6] Summary statistics exclude data from 1996 (HKP 1997) due to suspected errors with this data.

(blue) indicates a mean concentration greater than the BCSQG TEL.

(orange) indicates a mean concentration greater than the BCSQG PEL.

exceeded the TELs for arsenic, copper, iron and manganese in upper Hazeltine Creek (W7; Table 3.2), and the TELs for arsenic, iron, manganese and nickel in lower Hazeltine Creek (W11; Table 3.3). As discussed in more detail in the methods section (Section 4.1.3), TELs represent concentrations below which adverse biological effects are expected to occur rarely (CCME 1999). They do not take into account the geochemical conditions of the sediment and do not effectively represent concentrations above which biological effects are expected, particularly in naturally mineralized areas such as those in the vicinity of the Mount Polley Mine. As applied herein, they provide benchmarks to identify metals with elevated pre-event concentrations and to focus the sediment quality assessment on parameters of interest.

Subsequent to baseline, the characterization of sediment quality in whole sediment from upper Hazeltine Creek (Beak 2000; Minnow 2009; Minnow 2011; Minnow 2013b; Minnow 2013c), has confirmed that concentrations of copper, iron and manganese were present at concentrations greater than TELs, or greater than the probable effect level (PEL; BCMoE 2015a) in the case of manganese (Table 3.2). PELs represent concentrations above which adverse biological effects are expected to occur frequently (CCME 1999). As noted above, they do not take into account the geochemical conditions of the sediment or conditions in naturally mineralized areas such as those in the vicinity of the Mount Polley Mine. Elevated concentrations of arsenic were not apparent subsequent to baseline, but mean concentrations of chromium, nickel and selenium have been observed at concentrations greater than TELs during one or more sampling events (Table 3.2). Of these analytes with mean concentrations elevated above TEL or PEL, concentrations of chromium, copper, nickel, and selenium were highest during the most recent sampling events (2013; with the exception of 1996 data). However, these higher concentrations in recent sampling years appeared to be associated with the higher content of fine particles and organic carbon captured in sampling (Table 3.2). Although not displayed in Table 3.2, sediment quality data for the <63 µm sediment fraction (silt and clay) from upper Hazeltine Creek (reported in a MSc. thesis; van Lipzig 2011) confirmed that mean chromium, copper, iron, manganese, nickel, and selenium concentrations were elevated above TEL within upper Hazeltine Creek, and also reported a mean arsenic concentration (6.83 mg/kg) greater than the TEL. This elevated arsenic concentration, which was not observed in the upper Hazeltine Creek sampling results for whole sediment between 1999 and 2013 (Table 3.2), may be due to the analysis of the fine sediment fraction (<63 µm) by van Lipzig (2011).

The characterization of sediment quality in whole sediment from lower Hazeltine Creek following the baseline studies (Beak 2000; Minnow 2009; Minnow 2011; Minnow 2013b) indicated that the same four analytes which were identified as elevated relative to TELs in 1995 (arsenic, iron, manganese, and nickel) remained elevated, and were generally present at concentrations similar to baseline (Table 3.3). The highest concentrations of selenium in lower Hazeltine Creek have been observed in the most recent sampling event in 2013 (with the exception of 1996 data), and appeared to be associated with higher organic carbon content (Table 3.3). Selenium has been identified as an analyte of interest for the Mount Polley Mine (Minnow 2014a), and as a result, the data set that exists for selenium is larger than those for other analytes in both upper and lower Hazeltine Creek (Tables 3.2 and 3.3). Sediment quality data for lower Hazeltine Creek was also reported by Karimlou (2011) and van Lipzig (2011) for the fine sediment fraction (<63 µm). Results from these two MSc. theses were not included in Table 3.3, but confirmed that mean concentrations of arsenic, iron, manganese, and nickel were elevated above TELs. In addition, mean concentrations of chromium, copper, selenium and zinc also exceeded TELs at lower Hazeltine Creek sampling areas (Karimlou 2011; van Lipzig 2011), and were higher than concentrations for these analytes characterized in whole sediment between 1999 and 2012 (Table 3.3). This is likely a result of the analysis of the fine sediment fraction by Karimlou (2011) and van Lipzig (2011). For both upper and lower Hazeltine Creek, summary statistics (mean, 95th percentile, maximum; Tables 3.2-3.3) were calculated from all raw sediment quality data (Appendix Tables A.1-A.2), with the exclusion of 1996 data (the results for which included clear outliers). Calculated 95th percentiles represent the historical reference values for each upper and lower Hazeltine Creek, and were used for interpretation of the 2014 Hazeltine Creek sediment quality data presented in this report to identify analytes meaningfully greater than historical reference.

The benthic invertebrate community of Hazeltine Creek was evaluated during baseline studies in 1995, 1996 (HKP 1996; HKP 1997) and during mine operations in 1999 and 2007 (Beak 2000; Minnow 2009). Benthic community indices (Table 3.4) were calculated based only on taxa that were included in the analysis of 2014 benthic invertebrate community data collected for this report (i.e., to ensure defensible comparisons, taxon exclusions outlined in Section 4.5.3 were applied to the historic data). In addition, taxon counts for larval, juvenile, or indeterminate organisms in historic data were considered redundant where an adult stage had been identified for the same taxon, and were excluded from taxon richness calculations. The benthic invertebrate community characteristics of upper and lower Hazeltine Creek were relatively stable from 1995 to 2007 (Table 3.4), with the exception of lower benthic invertebrate densities for both upper

Table 3.4: Benthic invertebrate community indices measured in erosional areas of upper and lower Hazeltine Creek, 1995 - 2007 [1].

Location	Date	Data Source	Mean Density (organisms/m^2)	Mean Taxon Richness	EPT (%)	Sampling Method

	1996 - Oct 13	HKP (1997)	3,133	5	13	Soup Can
	1999	Beak (2000)	13,345	34	74	Surber
	2007	Minnow (2009)	32,596	42	53	Surber

[1] Taxa which were excluded from the benthic invertebrate endpoint calculations for the 2014 data (see section 4.5.3) were also excluded from the density and taxon richness calculations for the displayed historic data. Hydracarina were not identified beyond this taxonomic level in 1999 data for W7 and W11 (Beak 2000), or 1996-Oct 6 data for W11 (HKP 1997); Hydracarina (where present) were identified to lower taxonomic levels for all other displayed data sets. Ceratopogonidae (where present) were identified beyond the family level for all data sets except 1995-Oct 9 for W7 and W11 (HKP 1996).

and lower Hazeltine Creek (W7 and W11) in 1996 (HKP 1997). For lower Hazeltine Creek (W11), these lower densities may have been a result of the differing sampling methods in comparison to other years (Table 3.4). Taking all sampling years into account, Upper Hazeltine Creek had densities ranging between approximately 7,721 to 52,330 organisms/m^2, a taxon richness of 30 to 41, and a high proportion (43 to 76%) of metal intolerant taxa of the orders Ephemeroptera, Plecoptera, and Trichoptera (EPT; mayflies, stoneflies, and caddisflies). The benthic invertebrate community of lower Hazeltine Creek, excluding data from 1996 (HKP 1997 due to unusual collection methodology and associated outlying results), had densities of approximately 6,059 to 39,003 organisms/m^2, taxon richness of 22 to 42, and a similarly high proportion metal intolerant EPT taxa (45 to 74%; Table 3.4). Community condition observed in 2007 (Minnow 2009) was similar to baseline, and the continued dominance of metal intolerant EPT taxa in Hazeltine Creek was considered indicative of good ecosystem health. The benthic community data collection in 2007 (Minnow 2009) in upper and lower Hazeltine Creel was conducted using an approach consistent with the Environmental Effects Monitoring (EEM) program under the Metal Mining Effluent Regulations (MMER) of the federal *Fisheries Act* (Environment Canada 2012a; Government of Canada 2015). These 2007 data for Hazeltine Creek and the associated reference areas (in Cedar and Whiffle Creeks) can therefore be used in the future for a before-after-control-impact approach to assess benthic invertebrate community recovery within Hazeltine Creek over time.

3.3 Polley Lake

The sediment quality of Polley Lake has been assessed both prior to the development of the mine, as part of baseline studies conducted for Mount Polley Mine in 1989, 1995, and 1996 (Imperial Metals 1990, HKP 1996, HKP 1997), as well as following the initiation of mine operations (Beak 2000; Minnow 2011, 2013b). Metal concentrations reported in 1989 (Imperial Metals 1990) and October 1996 (HKP 1997) were based on the <0.149 mm and <63 µm sediment fractions, respectively.

Sampling has been conducted within the two deepest areas of Polley Lake (Stations P1, P2, and L; 30 to 36 m depth), as well as at several mid-depth areas throughout the lake (approximately 0.5 to 20 m depth; Figure 3.2). The characterization of sediment quality during baseline (Imperial Metals 1990, HKP 1996, HKP 1997) reported concentrations of chromium, copper, manganese, mercury, and nickel for all sampling events above the TELs (Table 3.5; Appendix Table A.3), and concentrations of arsenic, cadmium, iron, and selenium elevated above TELs during one or more sampling events. Baseline concentrations of copper also exceeded the PEL in all instances (with concentrations up

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.
[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b) - TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.
[3] Station L assessed in 1989 is equivalent to station P2 assessed in following sampling years. Concentrations reported in 1989 were for the <0.149mm fraction only. Station depths for 1989 were approximated from a bathymetric map.
[4] Concentrations reported in October 1996 were for the silt and clay (<63µm) fraction only.
[5] Summary statistics for mid-depth areas include data from stations B (1989), PL-1 to PL-5 (May 2009), A to C (October 2009), and POL-1 to POL-5 (2012).
[a] Particle size fractions for these samples are as follows: sand (0.053mm-2.0mm), silt (0.002mm-0.053mm), clay (<0.002mm).
[b] Particle size results for this station are based on one composite sample and the size fractions are as follows: sand (2.0mm-0.0705mm), silt (0.0705mm-0.0041mm), clay (<0.0041mm).
[c] Particle size results for this station are based on one composite sample,and the size fractions are as follows: sand (2.0mm-0.0675mm), silt (0.0675mm-0.0041mm), clay (<0.0041mm)
[d] Particle size fractions for these samples are as follows: sand (2.0mm-0.063mm), silt (0.063mm-0.0040mm or 0.0039mm), clay (<0.0040mm or 0.0039mm)
[e] Reported sand fraction also included silt and clay fractions (< 0.002mm-2mm).

(blue) indicates a mean concentration greater than the BCSQG TEL.
(orange) indicates a mean concentration greater than the BCSQG PEL.

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.
[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b) - TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.
[3] Station L assessed in 1989 is equivalent to station P2 assessed in following sampling years. Concentrations reported in 1989 were for the <0.149mm fraction only. Station depths for 1989 were approximated from a bathymetric map.
[4] Concentrations reported in October 1996 were for the silt and clay (<63µm) fraction only.
[5] Summary statistics for mid-depth areas include data from stations B (1989), PL-1 to PL-5 (May 2009), A to C (October 2009), and POL-1 to POL-5 (2012).
[a] Particle size fractions for these samples are as follows: sand (0.053mm-2.0mm), silt (0.002mm-0.053mm), clay (<0.002mm).
[b] Particle size results for this station are based on one composite sample and the size fractions are as follows: sand (2.0mm-0.0705mm), silt (0.0705mm-0.0041mm), clay (<0.0041mm).
[c] Particle size results for this station are based on one composite sample,and the size fractions are as follows: sand (2.0mm-0.0675mm), silt (0.0675mm-0.0041mm), clay (<0.0041mm)
[d] Particle size fractions for these samples are as follows: sand (2.0mm-0.063mm), silt (0.063mm-0.0040mm or 0.0039mm), clay (<0.0040mm or 0.0039mm)
[e] Reported sand fraction also included silt and clay fractions (< 0.002mm-2mm).

(blue) indicates a mean concentration greater than the BCSQG TEL.
(orange) indicates a mean concentration greater than the BCSQG PEL.

to 385 mg/kg), and iron and manganese exceeded the PEL during one or more sampling event. Only one sample was collected during baseline studies from mid-depth areas in Polley Lake (Station B; Imperial Metals 1990), with reported concentrations of copper and manganese exceeding the TEL (Table 3.5). It should be noted that metal concentrations reported for 1989 (Imperial Metals 1990) and October 1996 (HKP 1997) were based on the <0.149 mm and <63 µm sediment fractions, respectively.

Following the initiation of mine operations, evaluation of whole sediment quality from the basin stations within Polley Lake has confirmed that arsenic, cadmium, chromium, iron, manganese, mercury, nickel, and selenium remained at concentrations higher than TEL (Table 3.5; Appendix Table A.3). Concentrations of copper, which are locally elevated and were above PEL during baseline, remained above PEL (with concentrations up to 369 mg/kg observed in 2012). Manganese concentrations increased approximately two-fold relative to concentrations observed prior to and including 1999 (at station P2 only) with the highest concentration reported for the most recent sampling event in 2012 (Minnow 2013b). Similarly, the highest observed concentrations for selenium and molybdenum were reported for the most recent sampling event (2012), with concentrations approximately 3 to 4 times higher than those reported during or prior to 1999. Silver concentrations were above TEL subsequent to baseline, but these were due to a method detection limit above the TEL (Table 3.5). Such increases must be interpreted with caution because baseline sediment collections were conducted using an Ekman grab or ponar (Imperial Metals 1990; HKP 1996; HKP 1997) whereas subsequent collections were by gravity corer which generally collects fine surficial sediment more effectively. Within mid-depth sampling areas, studies subsequent to baseline (Minnow 2011; Minnow 2013b) have confirmed that copper concentrations remained elevated above TEL, however were also found to be higher than the PEL (Table 3.5). Mean concentrations of arsenic, nickel, selenium, and silver also exceeded TEL subsequent to baseline studies (Table 3.5), whereas concentrations of these analytes were below TELs during baseline. Silver concentrations, however, were all below the detection limit.

Concentrations of selenium at mid-depth stations were highest during the most recent sampling year (Minnow 2013b), but were also associated with higher total organic carbon content in the sediment than in other sampling years (Table 3.5). Similar to the basin sediment results, these observed differences in sediment quality at mid-depth stations over time must be interpreted with caution because higher metal concentrations observed in 2009 and 2012 were associated with a higher content of fine sediment particles captured (< 63µm), and the baseline sediment quality data was based on one sample.

Summary statistics (mean, 95th percentile, maximum; Table 3.5) were calculated for both the basin and mid-depth sampling areas within Polley Lake from all raw sediment quality data for each area (Appendix Table A.3). Calculated 95th percentiles represent the historical reference values for each of the basin and mid-depth sampling areas of Polley Lake, and were used for interpretation of the respective 2014 Polley Lake sediment quality data (for basin or mid-depth areas) presented in this report. For mid-depth sampling areas, 95th percentile historical reference values could only be calculated for the reduced set of analytes reported, and as such there is a reduced list of historical reference values for use in interpretation of 2014 data.

The benthic invertebrate community of Polley Lake was assessed during baseline studies (1989-1996) as well as in 1999. All samples were collected within each of the two deep basins (P1 and P2 or L) with the exception of the benthic invertebrate samples collected at the mid-depth station B in 1989 (Figure 3.2). Similar to the approach used for the Hazeltine Creek benthic community data, benthic community indices (Table 3.6) are based only on taxa that were included in the analysis of 2014 benthic invertebrate community data in the present report (i.e., to ensure defensible comparisons, taxon exclusions outlined in Section 4.5.3 were applied), and taxa considered redundant (counts of larval, juvenile, or indeterminate organisms where an adult stage had been identified for the same taxon), were excluded from taxon richness calculations. Within the basins of Polley Lake, the density of the benthic invertebrate community ranged from 77 to 1,048 organisms/m^2, and taxon richness ranged from 1 to 12 (Table 3.6). The temporal differences in benthic invertebrate density and taxon richness within each station are quite large, with the highest values observed in 1999 at both P1 and P2. For instance, mean invertebrate densities in 1999 observed at P1 and P2 were 4 and 13 times higher, respectively, than those measured in October 1995, and taxon richness was 6 and 8 times higher, respectively (Table 3.6). Although there may be some differences in taxon richness values among sampling years due to the level of identification achieved by differing taxonomists (Table 3.6) the reasons for the large differences in density among years are unclear given that detailed sample collection and laboratory processing protocols are not available. The large differences in benthic invertebrate density among years should be considered in the interpretation of results collected in 2014. Benthic invertebrate community species composition in Polley Lake has been dominated by Chironomidae (midges) and Oligochaetae (worms).

Table 3.6: Benthic invertebrate community indices in Polley Lake, 1989 - 1999 [1].

Date	Data Source	Location	Depth (m)	Mean density (organisms/m²)	Mean taxon richness	Sampling Method
1989 - Aug	Imperial Metals (1990) [2]	B	8	1,685	11	Standard ponar; 355 µm seive used in laboratory
		L [3]	20	77	4	Standard ponar; 355 µm seive used in laboratory
1995 - May	HKP (1996)	P1	30.7	417	3	Ekman; 200 µm seive used in laboratory
		P2	30.4 - 30.7	139	2	Ekman; 200 µm seive used in laboratory
1995 - Oct	HKP (1996)	P1	26.5	104	2	Ekman; 200 µm seive used in laboratory
		P2	26.5	78	1	Ekman; 200 µm seive used in laboratory
1996 - May	HKP (1997)	P1	31	87	1	Ekman; unspecified seive size
		P2	30.5	235	2	Ekman; unspecified seive size
1999 - Aug	Beak (2000)	P1	18	448	12	Petite ponar; 200 µm seive size
		P2	18	1,048	8	Petite ponar; 200 µm seive size

[1] Taxa which were excluded from the benthic invertebrate endpoint calculations for the 2014 data in the present report (see section 4.5.3) were also excluded from the density and taxon richness calculations for the displayed historic data. Taxa identified as Hydracarina were not identified beyond this taxonomic level in data from October 1995 (HKP 1996) and 1999 (Beak 2000); Hydracarina (where present) were identified to lower taxonomic levels for all other data sets. Ceratogonidae (where present) were identified beyond the family level for all displayed data sets.

[2] Density and taxon richness values shown for 1989 data are based on single samples and are not mean values.

[3] Station L assessed in 1989 is equivalent to station P2 assessed in following sampling years.

3.4 Bootjack Lake

Sediment quality in Bootjack Lake has been characterized both prior to mine development during baseline (Imperial Metals 1990, HKP 1996, HKP 1997), as well as following baseline (Beak 2000; Minnow 2011, 2013b). Sampling has been conducted within the two deepest areas (basins) of Bootjack Lake (B1, B2, LN, and LS; 10 to 17 m depth), and within several mid-depth stations throughout the lake (3 to approximately 12 m depth; Figure 3.3), although sampling efforts have generally been focused within the deep basin areas. Sediment quality of the basin areas sampled during baseline studies (Imperial Metals 1990, HKP 1996, HKP 1997) have shown concentrations of manganese, mercury, and nickel above the TEL guidelines, and concentrations of copper above the PEL in both basins for all baseline sampling events (Table 3.7; Appendix Table A.4). In addition, concentrations of arsenic, chromium, iron, and selenium have exceeded the TEL during one or more sampling events (Table 3.7). The sediment quality of mid-depth sites was evaluated at two stations during the 1989 baseline study (Imperial Metals 1990), and reported concentrations of arsenic, chromium, iron, manganese, and nickel exceeded TELs at one or both stations, and copper concentrations exceeded the PEL at both stations (Table 3.7). Metal concentrations reported for 1989 (Imperial Metals 1990) and October 1996 (HKP 1997) were based on the <0.149 mm and <63 µm sediment fractions, respectively.

The assessment of sediment quality in the deep basins of Bootjack Lake following mine development demonstrated that concentrations of arsenic, chromium, iron, manganese, mercury, nickel and selenium have remained elevated above the TEL, and concentrations of copper also remained higher than the PEL (Table 3.7). Sediment cadmium concentrations exceeded the TEL in 2009 (the highest reported cadmium concentrations), whereas cadmium concentrations during baseline were below TEL. This was also true for silver, however all silver results exceeding the guideline were less than the method detection limit (Table 3.7). Generally, sediment metal concentrations were similar both before and following the initiation of mine operations, with the exception of cadmium (discussed above), manganese, titanium, and vanadium (Table 3.7). Manganese concentrations were highest in the most recent sampling event (2012), and were approximately double those concentrations reported prior to and including 1996 (Imperial Metals 1990; HKP 1996; HKP 1997). Concentrations of both titanium and vanadium reported in 2009 and 2012 were approximately double those reported during 1999 sampling (concentrations of these metals were not reported prior to 1999).

(orange) indicates a mean concentration greater than the BCSQG PEL.

The limited sediment quality data available from mid-depth stations in Bootjack Lake subsequent to baseline confirmed the presence of arsenic and copper concentrations greater than TEL but not PEL (Table 3.7). Reported silver concentrations also exceeded the TEL, however were based solely on results less than the method detection limit. In general, the concentrations of analytes reported in 2009 for mid-depth sampling areas were lower than those reported during the 1989 baseline study. For instance, concentrations of chromium, and nickel which exceeded TEL during baseline were lower than TEL in 2009 (iron and manganese were not reported in 2009), and copper exceeded the PEL during the 1989 baseline study but exceeded only the TEL during the 2009 study. Results from the 2009 (Minnow 2011) study, however, are based on a single sample, and different sediment particle size fractions were used within these studies (bulk sediment in 2009 vs. <0.149 mm sediment fraction in 1989); therefore caution should be taken in interpreting these differences in analyte concentrations among studies. Selenium and total organic carbon were the only analytes measured during 2012 sampling (Minnow 2013b), and the mean selenium concentration reported in the most recent sampling year (2012) was higher than that reported in 2009, but was also associated with a higher organic carbon content in the sediment and within the range of selenium concentrations reported for the basins of Bootjack Lake (Table 3.7). Summary statistics (mean, 95th percentile, maximum; Table 3.7) were calculated for both the basin and mid-depth sampling areas within Bootjack Lake from all the raw sediment quality data (Appendix Table A.4). Calculated 95th percentiles represent the historical reference values for each of the basin and mid-depth sampling areas of Bootjack Lake, and were used for interpretation of the respective 2014 Bootjack Lake sediment quality data (for basin or mid-depth areas) presented in this report.

Similar to Polley Lake, the benthic invertebrate community of Bootjack Lake was assessed during baseline studies (1989-1996) as well as in 1999. The majority of sampling has been conducted within each of the two deepest areas of the lake (basins B1 and B2), with the exception of two mid-depth stations which were sampled in 1989 (stations B2 and B3; Figure 3.3). The benthic invertebrate community indices (Table 3.8) were calculated using the same methods described in Section 3.2 (i.e. taxon exclusions outlined in Section 4.5.3 were applied, and taxa considered redundant were excluded from taxon richness calculations). The density of the benthic invertebrate community varied widely among sampling years within the basin stations of Bootjack Lake, from 35 – 5,975 organisms/m^2, and taxon richness ranged from 1 to 23 (Table 3.8). The lowest observed density and taxon richness values occurred during the 1995 and 1996 baseline study years (HKP 1996; HKP 1997), while the values for these indices observed in 1999

Table 3.8: Benthic invertebrate community indices in Bootjack Lake, 1989 - 1999 [1].

Date	Data Source	Location	Depth (m)	Mean density (organisms/m^2)	Mean taxon richness	Sampling Method
1989 - Aug	Imperial Metals (1990) [2]	LN (North Basin)	12	5,975	16	standard ponar; 355 µm seive used in laboratory
		LS (South Basin)	11	364	8	standard ponar; 355 µm seive used in laboratory
		B2	9	172	5	standard ponar; 355 µm seive used in laboratory
		B3	3	1,570	8	standard ponar; 355 µm seive used in laboratory
1995 - May	HKP (1996)	B1	17.1	35	1	Ekman; 200 µm seive used in laboratory
		B2	15.7	217	2	Ekman; 200 µm seive used in laboratory
1995 - Oct	HKP (1996)	B1	14.6	246	2	Ekman; 200 µm seive used in laboratory
		B2	14.0	98	1	Ekman; 200 µm seive used in laboratory
1996 - May	HKP (1997)	B1	13.5	104	2	Ekman; unspecified seive size
		B2	13.5	226	3	Ekman; unspecified seive size
1999 - Aug	Beak (2000)	B1	10	3,524	15	Petite ponar; 200 µm seive size
		B2	11	3,076	23	Petite ponar; 200 µm seive size

[1] Taxa which were excluded from the benthic invertebrate endpoint calculations for 2014 data in the present report (see section 4.5.3) were also excluded from the density and taxon richness calculations for the displayed historic data. Hydracarina (where present) were identified beyond this taxonomic level for all displayed data sets except 1999-Aug (Beak 2000). Ceratopogonidae (where present) were identified beyond the family level in all displayed data sets.

[2] Density and taxon richness values shown for 1989 data (Imperial Metals 1990) are based on single samples and are not mean values.

(Beak 2000) were similar to those observed during the 1989 baseline study (Imperial Metals 1990). As with the Polley Lake benthic invertebrate community data (Section 3.3), there may be some differences in taxon richness values among sampling years due to the level of identification achieved by differing taxonomists (Table 3.8), however the reasons for the large differences in density among years are unclear because detailed sample collection and laboratory processing protocols are not available for all sampling years. Within mid-depth sampling stations (B2 and B3; 1989), density ranted from 172-1,570 organisms/m^2, and taxon richness ranged from 5-8 (Table 3.8). The large differences in benthic invertebrate density among years should be considered in the interpretation of results collected in 2014. Benthic invertebrate community taxon composition in Bootjack Lake among years has been dominated by Chironomidae and Chaoboridae (midges) and Oligochaetae (worms).

3.5 Quesnel Lake

The existing historical sediment quality data for Quesnel Lake is very limited, and to the best of our knowledge, there is no historical benthic invertebrate community data available. Efforts were made to obtain historical sediment quality or benthic invertebrate community data through contact with the BC Ministry of Environment and through publication lists provided by the Quesnel River Research Centre. Unfortunately, these search efforts did not result in acquiring historical data for either sediment quality or benthic invertebrate community, and a gap in historical data exists for Quesnel Lake. Sediment was collected in 2012 (Minnow 2013b) from a littoral sampling location in the North Arm of Quesnel Lake (Figure 3.4) and was analysed for total organic carbon content and selenium concentration. The mean selenium concentration measured in 2012 at the Quesnel Lake North Arm (0.37 mg/kg) was well below the TEL guideline (Table 3.9). The calculated 95th percentiles (Table 3.9) represent the historical reference values for these analytes, and were used for interpretation of the 2014 sediment quality data from littoral sampling areas of Quesnel Lake presented in this report.

4.0 SEDIMENT QUALITY IMPACT CHARACTERIZATION METHODS

The sediment quality impact characterization (SQIC) included physical, chemical and biological data collections to address the key questions outlined in Section 2.0. The SQIC included the following general components (Table 2.1):

- Sediment chemical characterization;
- Sediment geochemical characterization, including selective chemical extraction, shake flask testing, porewater chemistry, acid-base accounting, and particle size fractionation;
- Sediment core chemistry and porewater chemistry;
- Sediment toxicity testing;
- Benthic invertebrate community characterization; and
- Benthic invertebrate tissue chemistry.

Detailed descriptions of sampling, analytical and interpretive methodology associated with each of these general components are provided in the sections that follow. These sections outline: 1) the objective of the monitoring component; 2) an overview of the Study Design; 3) a detailed description of methodology and measurements; 4) a description of laboratory analyses; and 5) a description of how data were interpreted. Whenever possible, data collection methodology was consistent with recognized guidance for field sampling and analysis (e.g., the British Columbia Field Sampling Manual [BCWLAP 2003]; Technical Guidance for Environmental Effects Monitoring [Environment Canada 2012a]; Canadian Aquatic Biomonitoring Network Protocols [Environment Canada 2012b]).

Field data collection in support of the SQIC was undertaken between August 7th and October 26th 2014. Data were collected from potentially impacted areas located downstream of the Mount Polley Mine (based on the apparent debris field) as well as at unimpacted reference areas. Study areas (Figure 4.1) included:

- Hazeltine Creek (Figure 4.2);
- Polley Lake (Figure 4.3);
- Quesnel Lake (both littoral and profundal areas; Figures 4.4 and 4.5);

- Quesnel River (to QRCC; Figure 4.6);
- Lake reference areas (Bootjack Lake [Figure 4.3], Quesnel Lake upstream [Figures 4.4 and 4.5]); and
- River reference areas (Cariboo River and Clearwater River; Figure 4.6)

Within each of the study areas depicted in Figures 4.2 to 4.5, sediment samples were collected at a total of five replicate stations to facilitate statistical comparisons among areas in accordance with the study design depicted in Table 4.1. Although study components are discussed independently in the sections that follow, it must be noted that, at any given location, samples for the different program components were collected concurrently in order to optimize efficiency and data comparability (e.g., samples for basic chemistry, geochemical characterization, sediment toxicity and benthic invertebrate community characterization were typically collected on either the same day or on subsequent days for all sampling locations. The precise location of each sampling station is provided in Appendix Table B.1.

4.1 Sediment Physical and Chemical Characterization

The objective of the sediment physical and chemical characterization was to characterize the physical and chemical condition of sediments in potentially impacted areas relative to reference areas and pre-event conditions (where data are available). This includes the identification of parameters of interest (POIs) and indicator parameters (IPs) and the examination of their distributions through potentially impacted areas to determine the spatial extent of impact. POIs are defined as analytes that are elevated relative to effects-based guidelines and reference or background concentrations (Figure 4.7). IPs are defined as analytes that are not elevated relative to effects-based guidelines, but are elevated relative to reference and/or background by an average of two or more times at any exposed area (Figure 4.7).

Sediment physical and chemical characterization included the collection of sediment samples at a total of 102 stations within Hazeltine Creek, Polley Lake, Bootjack Lake and Quesnel Lake (Table 4.1; Figures 4.2 to 4.5). Within Hazeltine Creek, three areas (upper, middle and lower) were sampled (Table 4.2; Figure 4.2). In Polley Lake, two deep areas (the north and south basin, respectively) and two shallower areas were sampled, with two deep areas and one shallow area sampled within Bootjack Lake as reference (Table 4.2; Figure 4.3). Sampling in Quesnel Lake was also conducted at two depth strata - littoral (1.0 to 2.0 meter depth) and profundal (approximately 80 to 100 meters depth). Both the littoral and profundal sampling of Quesnel Lake included two reference areas as well as

[a] For Bootjack and Polley Lakes, samples collected by petite ponar for particle size and total organic carbon analysis were used for sediment geochemistry analyses where the sediment volume collected using the indicated sampling method was insufficient for the analyses.

[b] Additional grabs collected for field duplicate samples.

[c] Coring unsuccessful due to sediment consistency; petite ponar was used to collect sediment chemistry sample.

[d] Two additional toxicity samples collected at within this area, each comprised of a 5 ponar composite

[e] Additional grabs collected to provide sufficient sample volume for required analyses.

areas designated as near-field, far-field and far-far-field (Table 4.2; Figures 4.4 and 4.5). The identification codes used for sampling stations during field sampling differed from those that are used in the present report, and a key to the corresponding sampling codes is presented in Table 4.3.

4.1.1 Sample Collection

Sediment samples were collection from running waters of Hazeltine Creek, as a well as lake environments of Polley Lake, Quesnel Lake and Bootjack Lake. In Hazeltine Creek, sediment samples were collected using a stainless steel shovel. Sampling using a grab device (a petite ponar sampler) was attempted, but did not yield good samples due to limited penetration depth as a result of high sediment density. All Hazeltine Creek sediment samples were collected from wetted sampling stations that supported the accumulation of finer materials (i.e., small pools or backwaters). Five replicate stations were sampled to represent each sampling area (Table 4.2; Figure 4.2). At each sampling station, a composite sediment sample was prepared from five scoops of sediment collected with the shovel. Surficial sediment was carefully collected to ensure the capture of a uniform depth (top 3 cm) and to limit disturbance that could result in loss of fines. Each scoop was placed in a plastic tote. After five scoops were collected, the material within the tote was homogenized using a stainless steel spoon and transferred into four 250 mL glass sampling jars labeled with the project number, sample location and collection date. All sampling equipment was rinsed between stations using site water. Duplicate (split) sediment samples were collected at a target frequency of 10% for quality assurance / quality control (QA/QC) purposes. Supporting information collected at each sampling site included GPS (Geographic Positioning System) coordinates, sampling depth, field meter measurements of temperature, specific conductance, dissolved oxygen and pH (using a YSI EXO™ handheld portable field meter equipped with YSI EXO2™ Sonde), site photographs (including photographs of sediment samples), notes of the presence or absence of aquatic vegetation, and other physical observations (sediment texture, colour, density, etc.). Immediately after collection, samples were placed into a cooler with ice packs, where they were maintained cool prior to transport to the field laboratory where they were placed in a refrigerator and held until shipment to the analytical laboratory.

In Polley and Bootjack Lakes, sediments for the analysis of metal concentrations were collected using either a Kajak-Brinkhurst (KB) corer or a Tech Ops corer in accordance with technical guidance for gravity coring outlined in the British Columbia Field Sampling Manual (BCWLAP 2003) and the federal Technical Guidance Manual for Environmental

Effects Monitoring (EEM; Environment Canada 2012a), with the exception of one sampling station (see Table 4.2). Sediment samples for physical analysis (particle size distribution) and chemical analysis of total organic carbon (TOC) were collected using a petite ponar grab sampler. Briefly, the KB corer is a gravity corer that collects samples in 2” (5.08 cm) diameter core tubes. Core collection relies on a combination of surface tension within the core and suction supplied by a plunger that seals the top of the core tube after being deployed by a messenger. The Tech Ops corer is a gravity corer that collects samples in 4” (10.16 cm) diameter core tubes. Core collection relies on a combination of surface tension within the core and suction supplied by an automatic seal (plunger assembly) that shuts in response to sampler retrieval (upward pull). As with sampling areas in Hazeltine Creek, five replicate stations were sampled to represent each mid-depth sampling area (Table 4.2; Figure 4.3). However, at the basins, three replicate stations were sampled to represent each basin due to due to the small sampling area. Success rates for each of the core devices tended to vary with sampling location in accordance with sediment characteristics and both devices were used in the program (Table 4.2).

During coring, care was taken to control the rate at which the coring device was lowered, to maintain the corer in a vertical position during descent and to allow the corer to penetrate the sediment with minimal sediment disturbance. The corer was then carefully retrieved to surface and an extruder head was inserted into the bottom of the core tube to prevent any sediment slippage. Core samples were rejected if there was evidence of slippage, that the core did not penetrate the substrate vertically, or that the sediment-water interface was disturbed within the core. The core tube was then removed from the corer and the extruder head was then used to push the sediment upwards towards the top of the core tube in a controlled fashion with care taken to minimize suspension of fines. In the event of suspension, momentum was stopped, allowing the solids to re-settle. Once the sediment was extruded to near the top of the tube, an extrusion collar marked in 1-cm intervals was carefully aligned on the top of the tube and the sediment extruded upwards into the collar. A core slicer was then carefully inserted between the tube and the collar at the 3-cm interval, to collect the top 3-cm of sediment, which was then transferred into three 250 mL glass sampling jar labeled with the project number, sample location and collection date. The procedure was then repeated twice more if using the Tech Ops corer or approximately nine times more if using the KB corer to provide a composite sample of sufficient volume for the required analyses. All sampling equipment was rinsed between stations using site water. As indicated above, duplicate (split) sediment samples were collected at a target frequency of 10% for quality assurance/quality control (QA/QC) purposes and supporting information was collected at each sampling site. Immediately after collection, samples were placed into a cooler with ice packs, where they were maintained cool prior to transport to the field laboratory where they were placed in a refrigerator and held until shipment to the analytical laboratory.

In Quesnel Lake, sediment samples (both littoral and profundal) were collected using a stainless steel petite ponar grab sampler (15.24 cm x 15.24 cm; 0.023 m^2 sampling area) in accordance with technical guidance outlined in the British Columbia Field Sampling Manual (BCWLAP 2003) and the federal Technical Guidance Manual for Environmental Effects Monitoring (EEM; Environment Canada 2012a), with the exception of one sampling station (see Table 4.2). Two coring devices were tested in Quesnel Lake, but could not consistently retrieve sediment due to sediment texture (either hard sediment resulting in insufficient penetration depth, or soupy sediment resulting in loss of material from the core). Profundal grab samples (mean depth approximately 100 meters) were collected with the assistance of a commercial line hauler (Ace Line Hauler Brutus Plus 40). As with sampling areas in Hazeltine Creek and Polley Lake (mid-depth), five replicate stations were sampled to represent each sampling area (Table 4.2; Figures 4.4 and 4.5). At each station, composite samples of the top three centimetres of surficial sediment of five to fifteen acceptable petite-Ponar grabs (i.e., full to each edge of the sampler) were collected. Each petite ponar grab was collected into a plastic sampling tote and observed for completeness and any unusual characteristics. If the sample was deemed acceptable, surficial material to a depth of 3 cm was transferred to a second tote using a stainless steel spoon. Remaining sediment was discarded. The procedure was then repeated for all subsequent grabs. At that point, the material within the tote was homogenized using a stainless steel spoon and transferred into four 250 mL glass sampling jars labeled with the project number, sample location and collection date. All sampling equipment was rinsed between stations using site water. As indicated above, duplicate (split) sediment samples were collected at a target frequency of 10% for quality assurance / quality control (QA/QC) purposes and supporting information was collected at each sampling site. Immediately after collection, samples were placed into a cooler with ice packs, where they were maintained cool prior to transport to the field laboratory where they were placed in a refrigerator and held until shipment to the analytical laboratory.

Sediment samples were shipped to the analytical laboratory (ALS Environmental, Burnaby BC) at minimum frequency of weekly. Prior to shipment, samples were placed in a cooler with frozen ice packs and a chain-of custody form was prepared and packed with the samples. Coolers were shipped overnight for next day delivery to the analytical laboratory.

4.1.2 Laboratory Analysis

Upon receipt, ALS Environmental opened the cooler(s), measured temperature to verify the maintenance of cold samples, removed each sample from the cooler(s), logged the sample, and assigned each sample a unique sample identification code. A sample receipt confirmation was then sent to MPMC for verification.

Laboratory analysis included moisture content, pH, particle size distribution, total organic carbon content, total nitrogen concentration, and metal concentrations (Table 4.4). Total organic carbon content and metals were determined in bulk sediment (<2 mm diameter) in accordance with Canadian Council of Ministers of the Environment (CCME) protocol and also in the silt/clay fraction (<63 µm diameter) in accordance with recent recommendations by the British Columbia Ministry of Environment (BCMoE 2012). The former is more suitable for comparisons to sediments quality guidelines, which were based on chemical concentrations in bulk sediment (e.g., CCME 1999), while the latter have the advantage reducing variability that can arise due to the inclusion of larger particles. In programs targeting fine sediments, particularly in lakes, differences would be expected to be small. In receiving environments, all else being equal, one would expect enrichment in finer fractions (Horowitz and Elrick 1987; Horowitz 1991). However, this is based on an assumption of a dominant influence of surface sorption processes in defining metal concentrations and may not apply in the case of one major anthropogenic input. Upon completion of the analyses, data reports were provided by ALS Environmental to MPMC electronically in Adobe Acrobat Portable Document Format (PDF) and as MSExcel files.

4.1.3 Data Analysis

Upon receipt of the analytical data, data files were managed by MPMC. Prior to use in data analysis and interpretation, a Data Quality Assessment (DQA) was completed by Minnow and included an examination of data completeness, method detection limits achieved, laboratory precision, laboratory accuracy, and field precision. The DQA process is described in more detail in Appendix C and resulted in some requests for re-analysis.

Following the completion of DQA, all sediment quality data were compiled for analysis in MSExcel. Sediment quality data were summarized, by area, by calculating mean, median, standard deviation, standard error, minimum and maximum. Data were then

evaluated in comparison to British Columbia Working Sediment Quality Guidelines for the protection of aquatic life (SQGs; BCMoE 2015a, 2015b), Contaminated Sites Regulation (CSR) standards (Government of British Columbia 1996), and reference concentrations.

SQGs are numerical criteria that are protective of sediment-dwelling organisms based on long-term exposure. Most British Columbia SQGs have been adopted from the CCME (CCME 1999) or from Ontario (OMOE 1993) and have two levels - an Interim Sediment Quality Guideline (ISQG) or Threshold Effect Level (TEL, occasionally also referred to as a Lowest Effect Level or LEL) and a Probable Effect Level (PEL, occasionally also referred to as a Severe Effect Level or SEL). The TEL represents the concentration below which adverse biological effects are expected to occur rarely, whereas the PEL represents the concentration above which adverse biological effects are expected to occur frequently (CCME 1999). Data from which many of the SQGs were developed were strongly weighted by data for Great Lakes basin sediments (e.g., Jaagumagi 1988; Jaagumagi et al 1989), which tend to have substantially lower natural content of many metals relative to sediments in mineralized areas (e.g., Prairie and McKee 1994). Therefore natural background and/or reference concentrations of sediment metals, particularly at mineralized areas of the Canadian Shield, can often exceed SQGs. It is also notable that the BCSQG are not based on cause-effect studies, but rather on correlative levels of substances found in the sediment where biological effects have been measured (i.e., co-occurrence data; BCMoE 2015a, 2015b). Therefore, caution should be exercised in the application of these guidelines.

CSR standards for sediment (Government of British Columbia 1996) are sediment quality standards that were developed to assist in determining whether sediments are contaminated, and if sediment clean up proceeds, whether they meet remediation criteria (BCMoE 2005). CSR standards have been defined for a limited number of analytes in two levels of sediment - sensitive and typical (Government of British Columbia 1996). Sensitive sediment is defined as sediment at a site with sensitive aquatic habitat and for which sensitive management objectives apply and typically apply to sediments in the ecologically active zone (top one meter) of an aquatic receiving environment (BCMoE 2013). Typical sediment is defined as any sediment that is not sensitive sediment, and generally apply to sediments below the ecologically active zone (top one meter) of an aquatic receiving environment (BCMoE 2013). Thus, CSR standards for sensitive sediment apply to Hazeltine Creek and Quesnel Lake littoral sediments, and CSR standards for typical sediment apply to Polley Lake and Quesnel Lake profundal sediments. Lastly, reference values also fall into two categories - pre-event data and data collected at reference sites in 2014. Pre-event and reference data were compiled and used to calculate reference screening values. For each pre-event or reference dataset, 95th percentile values were calculated and compared. The highest pre-event or reference 95th percentile value was then used to screen the data from the exposed areas to identify analytes present in impacted areas at concentrations greater than pre-event and/or reference.

Collectively, guidelines and references values were used in a two-way screening to classify analytes into four categories as depicted in Figure 4.7:

1. Those whose concentrations are lower than guideline and reference;
2. Those whose concentrations are greater than guideline but not reference;
3. Those whose concentrations are lower than guideline (or for which no guideline exists) but greater than reference; and
4. Those whose concentrations are greater than both guideline and reference.

This screening process was used to define Parameters of Interest (POIs) and Indicator Parameters (IPs). POIs are defined as analytes in Category 4 (those with concentrations are greater than both guideline and reference) and IPs are defined as analytes that fall into Category 3 (those with concentrations lower than guideline [or for which no guideline exists] but greater than reference). All POIs were examined in detail in comparison to all guidelines (both BCSQG and CSR standards) and in comparison to all reference values (both pre-event and unexposed reference). IPs were examined for the magnitude of elevations in relation to reference, and all IPs elevated by a factor of two or more were examined in the same manner as the POIs. IPs that were elevated by a factor of less than two, and analytes that fall into categories 1 and 2 were not examined further.

Sediment quality data were also summarized using Principal Components Analysis (PCA). PCA is a multivariate statistical ordination technique that can be used to reduce a large number of environmental variables and to assist in the identification of patterns in datasets. In this case, PCA was used to reduce the sediment metals data (32 analytes; Table 4.4) and to assist in the identification of which metals best explain variability with the datasets (spatial variability). The former serves to reduce the number of variables considered in examining relationships and the latter serves to augment the identification of POIs and IPs. PCA was performed using the program PC-ORD© version 6 (McCune and Mefford 2011). Prior to running PCA, analytes for which 100% of the available data were below laboratory method detection limits (MDL), or analytes for which an incomplete dataset existed were excluded from the data matrix. All data points were then transformed using a logarithmic transformation (log [concentration x+1]) as concentration data are generally log-normally distributed. To ensure that each interpreted axis explained more variation in the dataset than by chance alone ($p<0.05$), a Monte Carlo randomization test was performed using 9999 randomized runs of the original dataset (McCune and Grace 2002). Principal component axes were then generated from the correlation matrix of the remaining sediment data and the results for the axes identified as significant were plotted to identify analytes that best explained similarities and differences in sediment chemistry among stations.

POIs and IPs were then subject to more detailed data analysis that included:

1. Plots in relation to all guidelines and reference values;
2. Examination of relationships to physical variables; and
3. Examination of geochemical data (see Sections 4.2 and 4.3).

Plots of all POIs and selected IPs were prepared in MSExcel. Plots provide average concentration with 95 percent confidence limit by area (i.e., bar charts with error bars). Available guidelines (BCSQG and CSR standards), reference concentrations, and background concentrations were added to the plots as lines to facilitate comparison of concentrations to these benchmarks.

Relationships between the POIs, IPs and PCA axes to physical variables (particle size) and other chemical variables (total organic carbon content) were evaluated using correlation analysis. Spearman correlation (often referred to a Spearman Rank-Order correlation) was competed using SPSS version 12.0 statistical software (SPSS 2003). Following the derivation of correlation coefficients, a Bonferroni-type correction (i.e., p-value [0.05] divided by the total number of correlations examined for independent variables) was applied to minimize the risk of declaring false positive correlations since at least 5% of derived correlations would be expected to occur by chance alone at an uncorrected p-value of 0.05. Any significant correlations found at the Bonferroni-adjusted p-value or at a p-value of 0.01 were further investigated using scatter plots to determine if a continuous distribution of data was realized (possible causal relationships) or if these relationships were “leveraged” by outlying points (or groups of points).

4.2 Spatial Extent

Characterizing the spatial extent of the influence of the dam failure on sediment quality is important to the effective characterization of impact. The objective of the spatial extent evaluation is to define the spatial extent of the physical disturbance associated with the event (physical erosion and deposition) as well as the spatial extent and magnitude of chemical disturbance. Characterization of the spatial extent of physical disturbance was based on observations made during the fieldwork (e.g., physical erosion in Hazeltine Creek, deposition within Hazeltine Creek, Polley Lake and Quesnel Lake), bottom / sub-bottom imaging conducted by Tetra Tech (discussed in detail in Tetra Tech 2015), and sediment chemical characteristics evident in chemical characterization. The evaluation of spatial extent, particularly in Quesnel Lake is based on the collection of a large number of sediment samples, providing a reasonable resolution within the constraints of sampling in three months (August through October 2014).

4.2.1 Data Collection

Characterization of the spatial extent of the influence of the dam failure on sediment quality was based on a combination of sediment quality and bottom/sub-bottom imaging. In addition to the sediment quality data previously described (Section 4.1.1), a total of 37 sediment samples were collected from Quesnel Lake between September 5th and 9th, 2014 to provide additional resolution of the spatial extent of the influence of the dam failure on sediment quality of Quesnel Lake (Figure 4.8). The samples were collected by Minnow and Tetra Tech using grab procedures similar to those previously described. Deviation from grab procedures described in Section 4.1.1 included the use of a Van Veen grab sampler (35.87 cm x 27.94 cm; 0.1 m^2) and no compositing of multiple grabs. Use of this larger sampler was possible because sampling was from the Tetra Tech oceanographic boat, which was available for a limited time period and was equipped with a large oceanographic winch. As with all other sediments collected as part of the SQIC, sediment from the top 3 cm of the grab sample was spooned from a tote into four 250 mL glass jars labeled with the project number, sample location and collection date. All sampling equipment was rinsed between stations using site water. Immediately after collection, samples were placed into a cooler with ice packs, where they were maintained cool prior to transport to the field laboratory where they were placed in a refrigerator and held until shipment to the analytical laboratory. A total of 33 of the 37 samples (including one composite sample) were submitted for analysis (Figure 4.8). Some samples that were well bracketed by others were held pending the receipt of analytical results and were ultimately not submitted as results for adjacent samples showed limited difference.

Bathymetric mapping and bottom/sub-bottom imaging was conducted by Tetra Tech between August 30th and September 6th 2014 and is described in detail under separate cover (Tetra Tech 2015). Briefly, Tetra Tech deployed an oceanographic boat from

minnow environmental inc.

Bothell, Washington (USA) to complete bathymetric mapping, imaging, and to assist with the collection of sediment samples for spatial delineation. Geophysical techniques focused on delineating the depositional footprint of the tailings dam failure within Quesnel Lake. Bottom mapping was undertaken using multi-beam bathymetry, acoustic sub-bottom profiling, and sidescan sonar throughout the west basin of Quesnel Lake. Equipment utilized for bottom mapping included a combination of an EdgeTech 2000-DSS 100/600kHz sidescan sonar, a 2-16kHz sub-bottom profiler and a RESON 7125 400kHz multibeam sonar. Mapping attempted to delineate bottom type and the thickness of deposited material based on reflectance and travel time.

4.2.2 Laboratory Analysis

Laboratory analyses for the delineation of spatial extent included a subset of the analyses conducted for physical and chemical characterization as described in Section 4.1.2. Specifically, analyses included particle size distribution, pH, moisture content, total organic carbon, total nitrogen, and metal concentrations in both the < 63 µm fraction and < 2 mm fraction.

4.2.3 Data Analysis

Delineation of spatial extent focused on the POIs and IPs identified as described above (Section 4.1.3). Concentrations of the POIs and IPs were superimposed on the bottom mapping competed by Tetra Tech using ArcGIS software (Esri ArcGIS 10.2.1 with Spatial Analyst). For the POIs and IPs, spatial extent was further characterized based on magnitudes of elevation. Specifically, ratios of the POIs and IPs at exposed stations relative to reference and/or pre-event data were calculated to reflect the magnitude of elevation. These ratios were tabulated to support the graphic depictions of spatial extent of sediment quality impact. Lastly, summaries of the biological findings (toxicity test results and benthic invertebrate community results) were also tabulated to further support the delineation of the spatial extent of sediment quality impact.

4.3 Sediment Geochemical Characterization

There are numerous factors that affect the mobility and bioavailability of sediment-associated metals. While metal concentrations that are below sediment quality guidelines provide a reliable indicator of an absence of biological effect, metal concentrations greater than sediment quality guidelines suggest the possibility of effect, but generally do not provide a reliable indication of effects. Therefore, a number of additional methods to evaluate potential effects were included in the SQIC. One of these additional methods is sediment geochemical characterization.

The objective of the sediment geochemical characterization is to provide information on the leachability/extractability of sediment-associated metals, which serves to provide insight into their potential mobility and bioavailability. Sediment geochemical characterization was undertaken in all depositional sampling areas (Table 2.1), and included a number of techniques:

- Selective chemical extractions;
- Shake flask tests;
- Porewater sampling and analysis;
- Acid-Base accounting;
- Particle Size Fractionation; and
- Sediment Stratigraphy Studies.

The manner in which each of these sediment geochemical characterizations contributes to understanding of the potential mobility and bioavailability is briefly described in the sub-sections that follow.

Selective Chemical Extractions

Most evaluations of sediment quality use strong acid digests to release sediment-associated metals for chemical analysis, generally referred to as "total metal". However, digestion by strong acid does not mimic any process that is likely to occur in a natural environment, nor does it reflect the fraction to which sediment-associated aquatic organisms could realistically be exposed. On the other hand, selective chemical extractions typically apply weaker reagents in an effort to mimic the fraction (or fractions) of sediment-associated metal that could be released under natural conditions. A number of selective chemical extraction schemes have been developed to better understand how and where metals are associated with sediments (mechanistic and "phase" approaches, respectively; Horowitz 1991). Although no scheme is likely to perfectly mimic mobilization under natural conditions (e.g., Kheboian and Bauer 1987; Tack and Verloo 1995), these selective extractions are useful in providing an indication of the fraction of "total" metal that could be mobilized under different circumstances and, importantly from the perspective of exposure characterization, the fraction of "total" that could not realistically be mobilized (e.g., Tessier and Campbell 1987).

Although many selective chemical extraction schemes have been proposed, the sequential extraction scheme of Tessier et al (1979) was selected for application to the

SQIC. Briefly, the “Tessier Procedure” involves five sequential extraction steps of increasing strength as outlined in Table 4.5. Results of the procedure will assist in determining the potential for elements to become bioavailable under changing chemical conditions (which may be chemically or biologically induced). The exchangeable, carbonate, reducible, and oxidizable fractions of the modified Tessier extraction method (Table 4.5) represent the fractions of sediment-associated metals that could be released under: 1) changes in ionic strength; 2) changes in pH; 3) reducing conditions such as those that could occur with diagenesis; and 4) oxidizing conditions (Tessier et al. 1979). The final digest in the procedure is a strong acid digest (concentrated nitric and hydrochloric acids) that mobilizes metals resistant to the first four digestion steps. The final digest in this procedure is the same digest used to mobilize total metals in the conventional chemical characterization described in Section 4.1.

Shake Flask Tests

As with selective extractions, a number of shake flask tests have been developed to mimic metal mobilization from sediment. These include tests designed to mimic mobilization with exposure to natural water (e.g., the Meteoric Water Mobility Procedure, the Synthetic Precipitation Leaching Procedure), exposure to acidified water (e.g., the British Columbia Special Waste Extraction Procedure), and to mimic toxicity characteristics (e.g., the Toxicity Characteristic Leaching Procedure). A simple shake flask test using deionized water was selected to provide an intuitive estimate of the relative mobility of sediment associated metals - a 3:1 deionized water to solid ratio, shaken for 24 hours (Price 1997). After 24 hours, solids are allowed to settle and supernatant was subject to chemical analysis as described below.

Porewater Sampling and Analysis

Sediments for porewater determinations were collected in Hazeltine Creek, in Polley Lake and in Quesnel Lake. As with the shake flask elutriates, porewater chemistry provides an indication of the relative mobility of sediment-associated analytes. Samples for porewater determinations in Hazeltine Creek were collected using the same techniques described above, whereas porewater collection from sediment core samples taken in Polley and Quesnel Lake was undertaken for the additional purpose of characterizing vertical patterns in redox and the implications for metal flux within sediment and from sediment to porewater and overlying water. The latter is described below under the sub-section entitled “Sediment Stratigraphy”.

Table 4.5: Sequential extraction method for sediment (modified Tessier procedure after Tessier et al. 1979), MPMC SQIC, 2014.

Step	Fraction	Reagent	Procedure	Fraction mobilized and mobilizing conditions
I	Exchangeable and Adsorbed	Magnesium chloride (1 M $MgCl_2 \cdot 6H_2O$)	1. Add 16mL of 1 M $MgCl_2 \cdot 6H_2O$ 2. Place on a shaker table of 1 hour 3. Centrifuge on high for 30 minutes 4. Pipette the supernatant into a centrifuge tube for analysis 5. Add 16 mL Deionized water into the tube with the sediment and hand shake one minute 6. Pipette supernatant 7. Discard supernatant	Fraction of trace metals that are likely to be mobilized by changes in water ionic composition
II	Carbonate Metal	Sodium acetate (1 M NaOAc)	1. Add 16 mL of 1 M NaOAc, adjust pH to 5 using Acetic Acid (HOAc) if necessary 2. Shake for 2.5 hours 3. Repeat steps 4-7 as in Step II	Fraction of trace metals that are susceptible to changes in pH
III	Easily Reducible and Iron Oxides	Hydroxylamine hydrochloride in acetic acid (0.1 M NH_2OH-HCl (25% V/V in HOAc))	1. Add 40 mL of 0.04 M 0.1 M NH_2OH-HCl solution 2. Hand shake for 1 minute 3. Place in the oven at 96 ± 3 ºC for 6 hours, hand shaking every hour 4. After 6 hours, remove from the oven and hand shake 5. Repeat steps 4-7 in step II	Fraction of trace metals that are mobilized under anoxic conditions
IV	Organic Bound Metal	Nitric acid then ammonium acetate (0.02 M HNO_3 then 3.2 M NH_4OAc)	1. Add 6 ml of 0.02 M HNO_3 2. Add 10 mL of 30% H_2O_2 and adjust to pH 2 with HNO_3 3. Hand shake for 1 minute. 4. Place in the oven at 85 ± 2 ºC for 2 hours 5. Shake at the end of one hour and two hours 6. Add 6 mL of H_2O_2(pH 2 with HNO_3)and hand shake 7. Heat to 85 ± 2 ºC for 3 hour. Shake every hour 8. Cool Sample 9. Add 10 mL of 3.2 M NH_4OAc in 20% V/V HNO_3 10. Add 8 mL H_2O (Dilute to 40mL) 11. Shake with a wrist shaker for 30 minutes 12. Repeat step 4-7 as in step II	Fraction of trace metals that are mobilized due to the degradation of organic matter under oxidizing conditions
V	Residual Metal	Aqua regia (CSR (EPA 200.2))	1. Add 10 mL DI water, 5 mL HNO_3 and 5 mL HCl 2. Cold digest for 60 minutes 3. Digest for 2 hours ± 15 minutes at sub-boiling reflux temperature 4. Cool 5. Bulk to 50 mls with DI water, cap and shake	Fraction of trace metals that are contained in minerals and are not expected to be mobilized over a reasonable time span under normal environmental conditions

Acid-Base Accounting

Acid-Base accounting is a procedure used to predict the drainage chemistry of tailings and waste rock. It is ultimately used to predict the potential of tailings to produce acid, as summarized in Net Neutralization Potential (NNP) or the Neutralization Potential Ratio (NPR; Price 1997).

Particle Size Fractionation

Particle size fractionation, the determination of chemistry and geochemistry of different particle size fractions, provides a characterization of potential geochemical differences in different particle size classes. This information can be used, in turn, to provide perspective on the geochemical characteristics of material that may have dispersed to lesser or greater distances within the receiving environment (i.e., coarse versus fine material, respectively). It is anticipated that smaller particle size fractions would be transported further downstream than coarser size fractions; therefore these data would assist in understanding metal transport associated with the tailings plume depositing particles.

Sediment Stratigraphy

Sediment stratigraphy studies were undertaken to determine vertical patterns in metal chemistry and the current post-depositional flux (if any) of sediment-associated elements from sediment / sediment pore-water into overlying lake water at two study areas - Polley Lake and Quesnel Lake (Figures 4.3 and 4.5). This included a determination of whether / where a redox boundary exists in the sediment horizon. The redox boundary (i.e., the depth where sediment or water becomes reducing) may be critical if it occurs at a shallow depth in sediments (i.e., where benthic invertebrates occur). If biologically active sediment becomes reducing, iron and manganese and associated metal(loids), may be released and become available to resident biota. Conversely, in oxidizing environments, organic matter may be bacterially degraded resulting in the release of metals associated with organics (e.g., copper). Vertical patterns of pore-water metal concentration, sediment metal concentration, sediment porosity data (obtained from a separate core), and overlying water metal concentrations can be used to characterize concentration gradients across the sediment-water interface and potential for metal loading from the sediment to the overlying water.

4.3.1 Sample Collection

Sediment samples for geochemical characterization were collected as previously described (Section 4.1.1), with the exception that all samples for sediment stratigraphy studies were collected by gravity coring using a Tech Ops corer as described in Section 4.1.1. The sample collected for particle size fractionation (from lower Hazeltine Creek; Figure 4.2), was collected in the same manner as other Hazeltine Creek samples, with the only difference being the collection of a greater volume (40 L) to accommodate laboratory fractionation by particle size.

All samples for geochemical characterization were treated in the same manner as described previously (Section 4.1.1) prior to their shipment to the analytical laboratory (ALS Environmental, Burnaby BC) at a minimum frequency of weekly. Prior to shipment, samples were placed in a cooler with frozen ice packs and a chain-of custody form was prepared and packed with the samples. Coolers were shipped overnight using Greyhound Express.

Sediment cores collected for sediment stratigraphy included cores collected from Polley Lake and from Quesnel Lake. Cores were collected from the near-field profundal area (108 m depth) of Quesnel Lake on September 1st, 2014 and from the Polley Lake Basins (P1 and P2; 29 m depth) on September 3rd and 4th, 2014. Core length varied with sediment density from 19 cm to 72 cm in length. All cores were capped and transported to the mine site for inspection and sectioning (which typically occurred the next day). On the day of core sectioning, the core was measured and photographs and notes were taken, identifying any observable horizons. The core was then mounted on the extruding apparatus (constructed in-house), and, using a pressure of no greater than 40 psi, water was used to slowly push an extruder bung up the core and thereby push the sediment up the core tube in 1 cm increments. Each sediment section was collected using a lexan collar (marked at 1 cm intervals) and a box slicer (stainless steel). If collecting sections for sediment chemistry, the section was placed into a re-sealable bag using a scraper. The scraper, collar and box slicer were cleaned between sections using site water. Each section was then placed in a cooler with ice packs until the samples could be frozen later the same day.

If the core was being sectioned for pore-water extraction and analysis, the following modifications were made to the method. The core sectioning table, core tube and all sectioning equipment were placed in a temporary glove bag, and prior to uncapping the sediment core, the glove bag was filled with nitrogen gas. A steady flow of nitrogen was maintained during the whole procedure, such that the glove bag always had a positive pressure applied to it. This prevented air (and oxygen) from entering the core sectioning environment, and maintained an inert atmosphere. Each sediment section was placed into an acid-washed plastic centrifuge tube (85 mL; polycarbonate), and capped securely. Once six sediment sections had been collected, the capped centrifuge tubes were removed from the inert atmosphere and placed in a centrifuge (Eppendorf Centrifuge 5804 R) that was refrigerated to 4°C. The samples were then centrifuged for 30 minutes at 10,000 g to separate the pore-water from the sediment, according to the US EPA method for pore-water extraction (USEPA 2001).

After centrifugation was complete, the capped centrifuge tubes were brought back into the inert atmosphere. Pore-water was extracted using nitrogen gas-purged plastic transfer pipettes, and preserved (when necessary). For metals analysis, samples were preserved using nitric acid; for sulphide analysis, samples were preserved using zinc acetate followed by sodium hydroxide addition; and samples for anions analysis required no preservative. All preservatives and sample vials for pore-water analysis were provided by the analytical laboratory, ALS Environmental (Burnaby BC). The pore-water samples were then capped, with a nitrogen gas headspace, removed from the inert atmosphere and placed in a cooler containing ice packs until they could be refrigerated the same day. Pore-water samples were shipped to the analytical laboratory on the same day or the next day, such that all analyte holding times were met (i.e., 8 days for sulphide analysis).

4.3.2 Laboratory Analysis

Selective Chemical Extractions

Selective chemical extractions were completed by ALS Environmental according to the modified Tessier sequential extraction procedure outlined in Table 4.5. Metals were determined by collision cell ICP-MS (inductively coupled plasma-mass spectrometry), with method detection limits as specified in Table 4.6.

Shake Flask Tests

Shake flask tests were completed by ALS Environmental according to the method described by Price (1997); a 3:1 deionized water to solid ratio was shaken for 24 hours. After 24 hours, solids were allowed to settle and supernatant was subject to chemical analysis for metals by ICP-OES (inductively coupled plasma-optical emission spectrophotometry) and mercury by CVAFS (cold vapour atomic fluorescence spectrophotometry; Table 4.6).

Porewater Sampling and Analysis

Hazeltine Creek sediment samples for porewater were processed using a different methodology that the core samples from Polley and Quesnel Lake described above (Section 4.3.1) due to much more coarse and dense substrate (core samples could not be collected). These sample were processed by ALS Environmental (Burnaby, BC), where they were centrifuged (using a Thermo Scientific Sorvall™ ST 40) at 3600 rpm for 15 minutes to separate water and solid. The supernatant was removed by pipette and subject to chemical analysis for hardness, total metals and dissolved metals using methods summarized in Table 4.6.

Acid-Base Accounting

Acid-Base accounting (ABA) was completed by ALS Minerals (North Vancouver, BC) in accordance with ABA Package 5 with the Sobek method (USEPA 1978; Table 4.7).

Particle Size Fractionation

The large (40 L) sediment sample for particle size fractionation was collected near the mouth of Hazeltine Creek (Station HAC50; Figure 4.2), dried and sieved at the analytical laboratory (ALS Environmental) to yield four particle size fractions: 1) sand (125 µm to 2 mm diameter); 2) very fine sand (63 µm to 125 µm diameter); 3) medium-coarse silt (25 µm to 63 µm diameter); and 4) clay and fine silt (< 25 µm diameter). Each of these fractions was subject to analysis for total metals and metals following the selective extraction procedure. Analytical procedures were as outlined in Tables 4.4 and 4.6.

Sediment Stratigraphy

Chemical analysis of sediment samples (1 centimeter slices) and extracted porewater samples collected as part of the sediment stratigraphy studies was completed by ALS Environmental according to the methods outlined in Table 4.4.

4.3.3 Data Analysis

Analysis of sediment geochemical data was generally similar to that applied to the general sediment physical and chemical characterization as described in Section 4.1.3. However, analysis of the geochemical data was focused on the POIs identified in analysis of the total metals data as they represent the analytes of greatest interest.

Table 4.7: Acid Base Accounting procedure (ABA5, Sobek Method), MPMC SQIC, 2014.

Parameter	Units	Method Description
Maximum Potential Acidity (MPA)	tCaCO3/1Kt	Sobek; % total sulphur * 31.25
Fizz Rating	Unity	addition of 1 or 2 drops of HCL to 0.5 g sample
Net Neutralization Potential (NNP)	tCaCO3/1Kt	MPA - NP
Paste pH	pH units	10 g sample saturated with de-ionized water; pH meter
Neutralization Potential (NP)	tCaCO3/1Kt	Sobek; 2.0 g sample treated with HCl until reaction is complete; titrated with NaOH to pH 7.0
Neutralization Potential Ratio (NPR)	Unity	NP / MPA
Total Sulphur (S) - Leco	%	0.1 g heated to 1350 °C under oxygen; Leco analysis of sulphur dioxide
Sulphate Sulphur (S) - HCl Leachable	%	Hydrochloric Acid (HCl) Leachable
Sulphate Sulphur (S) - Carbonate Leach	%	Sodium Carbonate (Na_2CO_3) Leach
Sulphide Sulphur (S) - Calculated Leco	%	Difference Calculation
Carbon Dioxide (CO_2)	%	0.02 g sample treated with Perchloric Acid ($HClO_4$) to evolve CO_2, measured by CO_2 coulometer
Inorganic Carbon (C)	%	Calculated from CO_2

Selective Chemical Extractions

Analysis of the selective chemical extraction data included the preparation of plots to characterize the apparent partitioning of POIs in sediment. For each POI, the dominant phase was identified and discussed relative to known environmental processes that could potentially mobilize the more easily extracted phases. POIs for which the majority of sediment-associated concentration was in potentially mobile forms were distinguished from those for which the majority of sediment-associated concentration was in a residual form. Concentrations of POIs in each phase and cumulative concentrations in the easily extracted phases (e.g., sum of Phase 1 through 3) were also screened using the same tools used to screen total metal concentrations (guidelines and reference as described in Section 4.1.3) in order to identify if concentrations in easily extracted phases alone might be present at concentrations of potential concern. Lastly, as described in Section 4.2.3, a spatial analysis was also completed to characterize any differences in partitioning and/or extractable concentrations relative to reference and with distance from the mine.

Shake Flask Tests and Porewater

Analysis of the shake flask and porewater data included a screening against British Columbia Water Quality Guidelines (BCWQG) for the protection of aquatic life (BCMoE 2015a, 2015b). It is not expected that that shake flask tests nor sediment porewater should meet BCWQG (which apply to surface waters); rather these were used to distinguish POIs with the potential to be released from sediments in potentially meaningful concentrations from those without that potential. As described in Section 4.2.3, a spatial analysis of shake flask test results and porewater chemistry was also completed to characterize any differences relative to reference and with distance from the mine.

Acid-Base Accounting

Acid-base accounting data were evaluated primarily on the basis of the Neutralization Potential Ratio (NPR). The NPR allows the classification of materials into four categories of potential Acid Rock Drainage (ARD): 1) likely (NPR <1); possibly (NPR 1-2); low (NPR 2-4) and none (NPR >4; Price 1997). A spatial analysis of NPR results was also completed to characterize any differences relative to reference and with distance from the mine.

Particle Size Fractionation

Particle size fractionation data were examined to characterize differences in POI concentrations in four different particle size classes (sand, very fine sand, medium-coarse silt, and clay/fine silt). In addition, concentrations of POIs in each fraction were screened against BCSQGs to evaluate whether the POIs (originally identified on the basis of BCSQG exceedences; Section 4.1.3) were elevated in each size category. Implications for dispersion within the receiving environment were considered.

Sediment Stratigraphy

Sediment porewater POI concentrations determined in sediment stratigraphy studies were evaluated as previously indicated for sediment total metals (Section 4.1.3) and porewater (above). However, the focus of these studies is the characterization vertical patterns of sediment metal concentrations and potential diffusive flux.

If sediment and pore-water metal concentrations suggest meaningful gradients, pore-water diffusive flux is based on the concentration gradient between the pore-water metal concentration in the top sediment section (0 to 1 cm), and the metal concentration in the overlying water. It considers diffusion and the random path-length that an ion diffuses through, given the particles that obstruct it. Other factors, such as attenuation of metals in sediment, are not considered in the calculation of diffusive flux.

Pore-water diffusive flux calculations were made according to Ullman and Allen (1982), using literature-based ideal solution diffusion co-efficients (Li and Gregory 1974) which were corrected for geometric tortuosity and the solution conditions of pore water to determine the bulk sediment diffusion coefficient, Dsi.

The equation for diffusive flux was as follows:

$$Ji = \Phi \times Dsi$$ Ullman and Allen (1982)

Where Ji is the flux of solute, i ($mg/cm^2/yr$); Φ is sediment porosity; and Dsi is the bulk sediment diffusion co-efficient of solute i.

Ideal solution diffusion co-efficients (Doi) for temperature conditions of 4°C were used in calculations, literature value diffusion co-efficients (Li and Gregory 1974) were corrected to 4°C using the Stokes-Einstein relationship. The literature value diffusion co-efficient for arsenic assumed the oxidized As(V) form, H_2AsO_4-, this is likely the appropriate oxidation state for Quesnel Lake, and the de-protonated form ($HAsO_4^{2-}$) is likely most appropriate for the pH of sediment in Quesnel Lake (pH 8.4) and Polley Lake (pH 7.45 and 7.90 in P1, and P2 respectively). The extra charge on the arsenic oxyanion would likely result in a slowing of diffusion, such that the calculated fluxes would be a conservative estimate. In a reducing environment, arsenite would predominate, ($H_3AsO_3^0$), which would have zero charge, and again, using the diffusion co-efficient for the di-protonate arsenate moiety would result in a conservative estimate for diffusive flux.

The bulk sediment diffusion co-efficient was calculated using geometric tortuosity, which is related to porosity (Boudreau 1996). Porosity for Quesnel Lake was determined using archived sediment sections (Φ=0.875), as sediment compaction had not occurred, the use of deeper sediment sections for this purpose was considered reasonable. The lower porosity for Quesnel Lake is fairly typical for very fine tailings material. Polley Lake porosity was taken to be 0.956, the highest porosity observed in sediment from both stations, this corresponded to a sediment density of 2.74 g/mL. This sediment density is slightly higher than that typically used for sandy sediment (2.5 g/mL; Cornett et al. 1989), which may be due to particle size differences.

4.4 Sediment Toxicity

The objective of the sediment toxicity testing program is to determine whether sediment affected by the tailings dam failure has the potential to cause adverse effects to aquatic life (e.g., Besser et al. 2015), and if so, to what spatial extent. It also forms one component of the sediment quality triad approach (concurrent sediment chemistry, toxicity and benthic invertebrate monitoring; Chapman 1990) to evaluating sediment degradation and associated biological implications. In considering sediment toxicity tests within a weight-of-evidence-approach (WEA), it must be considered that sediment toxicity tests employ laboratory cultured organisms that may not reflect the particular sensitivity/tolerance level of site organisms (Cairns and Mount 1990; Luoma and Rainbow 2008; Janssens et al. 2009), and that difference in survival and growth measured in sediment toxicity tests can be a result of physical factors (e.g., sediment texture and organic content) as well as contaminants (e.g., Ankley et al. 1994).

Sediment toxicity testing was conducted at all study areas (Table 2.1) concurrent with the sediment sampling for chemical and geochemical characterization (Sections 4.1 and 4.3), and was generally designed to allow statistical comparison among areas as depicted in Table 4.1. However, additional comparisons, defined a-priori, were made between near-field and far-field stations in Quesnel Lake and corresponding reference stations to characterize spatial variability at a smaller scale (Table 4.8). Two sediment toxicity tests were applied: 1) the 10-day survival and growth of *Chironomus tentans* (dilutus; a freshwater midge; Environment Canada 1997); and 2) the 14-day test of survival and growth of *Hyalella azteca* (an amphipod; Environment Canada 2013).

Table 4.8: Summary of statistical comparisons of sediment toxicity test results.

4.4.1 Sample Collection

Samples for toxicity testing were collected using a petite ponar grab sampler as described in Section 4.1.1. Each sample was generally a composite three to five grabs with the exception that within the profundal areas of Quesnel Lake, where 5 toxicity replicates were collected at each station, each toxicity replicate was composed of one grab (Table 4.2). Composited sediment was placed into 500 mL glass sampling jars labeled with the project number, sample location and collection date. In accordance with technical guidance (Environment Canada 2013), field replicates were used in the toxicity testing. For area comparisons, one replicate was collected from each station as outlined in Table 4.2. For the additional comparisons between near-field stations, far-field stations and reference stations in Quesnel Lake (Table 4.8), five-separate 500 mL field replicates were collected from of each five stations per area (i.e., 25 samples per area) using the same collection techniques and compositing approach. All sampling equipment was rinsed between stations or replicates using site water.

Following collection, sediment samples for toxicity testing were maintained cool (on ice or in a refrigerator) and then shipped to the toxicity test laboratory as soon as possible after collection. To the extent possible, sediments were held so that the testing could be run in appropriate batches that included sediments from the respective exposed and reference areas within a study creek or lake (i.e., Hazeltine Creek, Polley Lake, Quesnel Lake littoral and Quesnel Lake profundal). However, given the duration of the sampling program, some deviation from the ideal batch composition was required to ensure that sediments were held for no more than two weeks prior to testing.

4.4.2 Laboratory Analysis

Sediment toxicity tests were completed in accordance with technical guidance (Environment Canada 1997; 2013) by Nautilus Environmental (Burnaby, BC), which is certified by the Canadian Association for Laboratory Accreditation (CALA).

4.4.3 Data Analysis

Statistical analyses were conducted by Nautilus Environmental using CETIS (Comprehensive Environmental Toxicity Information System) software (Tidepool Scientific Software). All test results were statistically compared to concurrent laboratory controls. However, because tests for some areas were run in different batches, some normalization was required to make valid comparisons among batches. Specifically, in order to compare results between test batches, the test data were normalized to the underlying performance of the laboratory controls by dividing the data by the control response. This process resulted in removing the between-test differences in control performance. In the case of survival, the control response was normalized to the control acceptance criteria (i.e., 80% for H. azteca and 70% for C. tentans), and the samples were calculated as a percentage of normalized control performance. The samples were normalized to the control acceptance criteria, rather than to 100%, since there were cases where the performance of the samples exceeded the laboratory control performance, which would have produced normalized rates of survival exceeding 100%. For both species, weight data were normalized to the control value of controls run during the test with the reference site for that area. To normalize weight between tests, a weight correction factor was determined by dividing the average laboratory control growth for that specific test date by the average control growth for test corresponding to the reference site test. This correction factor was then applied to all replicates for that test date in order to correct for the differences in growth rates of the controls between tests.

The data normalization resulted in a dataset that could then be compared across test dates, since it removed the variance associated with differing growth and survival rates of the controls from the different test initiation dates. The normalized data were used to perform defined statistical comparisons among areas and stations (Table 4.8) using tests suited to the normality and variance (equal or unequal) of the particular dataset, and included the Fisher Exact Test, two-sample t-test, ANOVA and Fisher Exact / Bonferroni-Hommel test as selected using rules built in to the CETIS software. Statistical significance level was defined as $p = 0.05$. Sediment toxicity was identified as environmentally meaningful in cases where survival and/or growth were significantly reduced relative to laboratory control sediment (sand) and relative to field-collected reference sediment. In cases where toxicity was identified (statistically significant differences in survival and/or growth relative to laboratory and reference sediments), results were also evaluated relative to the spatial distribution of sampling areas.

Potential relationships between sediment toxicity and physical and chemical conditions of the study areas were explored using correlation analysis (e.g., Suter et al. 2015). In order to reduce the number of comparisons made, toxicity test results were compared to physical variables and to a reduced set of chemical variables (e.g., meter measures, sediment chemistry PCA axes, POIs and selected IPs as identified in the sediment quality data evaluation). Following derivation of correlation coefficients, a Bonferroni-type correction (i.e., a p-value of 0.05 divided by the total number of correlations examined for independent variables only) was applied to minimize the risk of declaring false positive correlations since at least 5% of derived correlations would be expected to occur by chance alone at an uncorrected p-value of 0.05. Any significant correlations found at the Bonferroni-adjusted p-value or at a p-value of 0.01 were further investigated using scatter plots to determine if a continuous distribution of data was realized (possible causal relationships) or if these relationships were “leveraged” by outlying points (or groups of points). Significant correlations, coupled with careful examination of scatterplots, were used to identify the factors that most contribute to variability in sediment toxicity. The causative merits of these factors were then considered in light of known physical and chemical mechanisms of toxicity.

Sediment toxicity test data were also integrated with the concurrently collected sediment chemistry and benthic invertebrate community data to apply a weight-of-evidence approach (WEA) to interpretation of potential effects of the tailings dam failure on sediment chemistry and aquatic life (i.e., the sediment quality triad; see Section 4.7).

4.5 Benthic Invertebrate Community

The objective of the benthic invertebrate community program was to characterize the influence of the tailings dam failure on benthic invertebrate communities. Benthic invertebrate community sampling also serves as an integral component of the sediment quality triad to assist in the evaluation of effects associated with the failure-derived material (i.e., concurrent sediment chemistry, toxicity and benthic invertebrate community monitoring; Chapman 1990). A secondary objective of the sampling was to provide post-event baseline data against which to track benthic invertebrate community recovery over time.

Benthic invertebrate community monitoring was conducted at all study areas (Table 2.1), with the exception of Hazeltine Creek. No benthic invertebrate community sampling was conducted in Hazeltine Creek in 2014 due to the absence of appropriate erosional habitat post-event (i.e., substrates were entirely fine materials derived from the tailings pond and scoured creek bed). Benthic invertebrate community samples were collected concurrent with, and at the same location as, sediment samples (Figure 4.1 to 4.5), and the sampling strategy was generally designed to allow statistical comparison among areas as depicted in Table 4.1. Within each area, five stations were sampled to provide adequate statistical power to definitively detect differences between the respective influenced and reference study areas (Environment Canada 2012a). Additional benthic samples were collected in the Quesnel River (six sites) for evaluation of potential failure-related effects using a Reference Condition Approach (RCA; Bailey et al. 2004). RCA reference sites included the Cariboo River, the Clearwater River, and the Blackwater River (Figure 4.6).

4.5.1 Sample Collection

Benthic invertebrate community samples were collected from lake environments (Polley Lake, Bootjack Lake and Quesnel Lake) and from running waters of the Quesnel River and associated reference areas. In lakes, samples were collected using grab techniques consistent with established provincial and federal protocols (i.e., BCWLAP 2003; Environment Canada 2012a). Benthic invertebrate samples were collected using a petite ponar grab sampler (often referred to as a petite ponar dredge sampler) with dimensions of 15.24 cm x 15.24 cm (6" x 6"). Five stations were sampled in each area to provide adequate statistical power to detect differences of ± two standard deviations at an α and β of 0.10. One sample was collected at each station and was a composite of five sub-samples (grabs; 0.116 m^2 of bottom area in total), to ensure that each sample was representative of the station. Upon retrieval, all samples were closely examined to verify that only high quality, comparable samples were retained (based on factors such as particle size, organic matter, presence or absence of plants or algae). Each grab was placed into a tub to evaluate whether the grab was complete (i.e., that the grab captured the surface material and was full to each edge) and to evaluate the depth to which the grab penetrated. Incomplete or unusual samples were discarded. Accepted grab samples were rinsed from the ponar into the tub to ensure the complete removal of all material. Sampling was repeated until five acceptable grabs were collected. Details about each acceptable grab were recorded on field sheets.

Composite samples collected from littoral areas of Quesnel Lake were then placed into a 500 µm mesh sieve bag and sieved free of all material less than 500 µm in diameter. Composite samples from Polley Lake, Bootjack Lake and the profundal areas of Quesnel Lake were placed into a 250 µm mesh sieve bag and sieved free of all material less than 250 µm in diameter. This difference in sieve sizes used in deep versus shallow lake areas reflects the lower productivity, smaller organism size and smaller average particle size of profundal environments (e.g., Ward 1992).

After sieving, the retained material (sample) from the five composited grabs was carefully transferred to labelled 1 or 2-L wide mouth plastic jars using a stainless steel spoon and a wash bottle while working over a plastic tub to avoid any potential loss of organisms. Any organisms that adhered to the sieve bag were removed and added to the sample. All samples were labelled internally (using wooden sticks) and externally with the station number, area identifier, project number, date and field personnel in order to ensure correct identification at the laboratory. Samples were preserved with buffered formalin solution to achieve a nominal concentration of 10%. Supporting information collected at each sampling site included GPS (Geographic Positioning System) coordinates, sampling depth, field meter measurements of temperature, specific conductance, dissolved oxygen and pH (using a YSI EXO™ handheld portable field meter equipped with YSI EXO2™ Sonde), site photographs (including photographs of sediment samples), notes of the presence or absence of aquatic vegetation, and other physical observations (sediment texture, colour, density, etc.).

Larger rivers, such as the Quesnel, are particularly challenging for biological assessment (e.g., Flotemersch et al. 2006). The depth, velocity, morphology, and substrate of the Quesnel River limits benthic invertebrate sampling to the littoral margins. To improve detection of potential impacts, habitat variability was reduced by standardizing the sampled habitat to the most consistent, biologically relevant, feasibly sampled habitat available throughout the Quesnel River. This was determined to be habitat of cobble littoral margins with water velocities of approximately 0.20 m/s, sampled at a depth of approximately 50 cm. Benthic invertebrate samples from the Quesnel River and associated reference areas were collected using a kick-and-sweep technique that was modified from the protocol developed under the Canadian Aquatic Biomonitoring Network (CABIN; Environment Canada 2012b).

The protocol involves a 3-minute travelling kick-and-sweep using a kick net with a triangular aperture measuring 36 cm per side and mesh having 400 µm openings. This type of sampling is best suited to substrate that is dominated by large cobble and boulder. During sampling, the field technician typically moves across the stream channel (from bank to bank, dependant on stream depth and width) in a ‘zig-zag’ pattern moving upstream for a timed kick of three minutes. With the net being held immediately downstream of the technician’s feet, the detritus and invertebrates are disturbed from the substrate and passively collected in the kick-net by the stream current. After three minutes of sampling time, the sampler stops and returns to the stream bank with the sample. The kick-net is rinsed with water to move all debris and invertebrates into the collection cup at the bottom of the net. The collection cup is then removed so the contents can be poured into a labelled plastic jar and preserved in a 10% buffered formalin solution. A single sample is taken at each area. This protocol was modified in two ways: 1) kick sampling occurred parallel to the shoreline at 50 cm of water depth, and 2) triplicate samples were taken and kick time was reduced from 3 minutes to 1 minute. The modification to sampling transect orientation was required due to the nature of the Quesnel River. The reduction of sample time was conducted to provide replication while maintaining the same level of overall search effort.

Immediately after completion of the three 1-minute kick-and-sweeps, material collected within the D-net was carefully transferred into a labeled one-litre, wide-mouth plastic jar. All samples were labelled internally (using wooden sticks) and externally with the station number, area identifier, project number, date and field personnel in order to ensure correct identification at the laboratory. Samples were preserved with buffered formalin solution to achieve a nominal concentration of 10%. Supporting information collected at each sampling site included GPS (Geographic Positioning System) coordinates, sampling depth, water velocity (using a Marsh-McBirney Flowmate Model 2000 portable velocity meter), stream width (using a Bushnell Yardace Pro Sport 450 range finder), stream depth, substrate characteristics, the type and relative coverage of any aquatic vegetation, water samples (with one field duplicate), field meter measurements of temperature, specific conductance, dissolved oxygen and pH (using a YSI 650 MDS field meter equipped with a YSI 600 XLM sonde that was calibrated daily), site photographs, notes of the presence or absence of aquatic vegetation, and other physical observations.

Supporting water quality samples were collected at all areas concurrent with benthic invertebrate community sampling. Samples were collected directly into pre-cleaned sample bottles provided by the laboratory and preserved (as required) immediately. Samples being analyzed for dissolved organic carbon (DOC) were collected into a clean container, filtered through a 0.45-μm membrane affixed to a sterile syringe, and transferred to an appropriate sample bottle. Water samples were collected by wading into a mid-channel area, moving from downstream to upstream, so as not to collect water downstream of disturbed substrates. All samples were collected at 25 cm depth where total water depth was 50 cm. Water samples were stored in coolers with ice packs. The samples were re-packed with ice for shipment to the analytical laboratory (ALS Environmental in Burnaby, BC) approximately each day or every other day.

All preserved benthic invertebrate samples were placed in coolers or totes and stored at the Mount Polley Mine prior to shipment to Cordillera Consulting (Summerland, British Columbia) for taxonomic analysis. Senior taxonomists at Cordillera Consulting are certified under the Taxonomic Certification Program of the Society of Freshwater Sciences (SFS) for benthic invertebrate taxonomy.

Supporting water samples were shipped in coolers on ice to ALS Environmental in Burnaby, BC, for analysis of dissolved organic carbon (DOC), total metals, dissolved metals, anions (nitrate, nitrite, sulphate, chloride, and fluoride), ammonia, total Kjeldahl nitrogen (TKN), total phosphorus, dissolved phosphorus, orthophosphate, alkalinity, hardness, turbidity, total suspended solids, total dissolved solids, pH, and conductivity.

4.5.2 Laboratory Analysis

Benthic invertebrate community samples were sent to Cordillera Consulting (lead taxonomist Sue Salter), in Summerland BC, for sorting and taxonomic identification using standard methods that incorporate QA/QC measures (e.g., Environment Canada 2002; 2012a; 2014). Taxonomists at Cordillera have achieved certification for Group 1 (general Arthropods West), 2 (Ephemeroptera, Plecoptera and Trichoptera East and West), and 3 (Chironomids West) benthic organisms in the Taxonomic Certification Program (http://nabstcp.atlanticwebfitters.ca/) of the Society for Freshwater Science (formerly the North American Benthological Society). Organisms were identified to the lowest practical level (LPL) (typically genus or species) using up-to-date taxonomic keys. Following identification, representative specimens of each taxon were placed in separate vials to create a reference collection for the project.

Briefly, upon arrival, each benthic sample was logged into proprietary software, followed by a check of proper preservation and the addition of Rose Bengal dye. Sample processing was initiated with sample washing, including elutriation to remove sand and gravel, with the remaining organic material examined to estimate the total number of invertebrates and preserved in 70% ethanol. If the estimated number of invertebrates was greater than 600 individuals and the sample was fine and non-clumping, a subsample was taken using a Marchant Box (Marchant 1989) as described by Environment Canada (2014). Of the 87 benthic samples collected from lake environments, only 11 required sub-sampling.

Samples (or sub-samples) were then sorted using a gridded Petri dish under low power stereo microscope into family/order while maintaining counts (but totals exclude Nemata, Platyhelminthes, Ostracoda, Copepoda, Cladocera, Collembola and any terrestrial drop-ins). When specimens were broken, only heads were counted towards the total, and larval and pupa exuviae were not counted. If the 300th organism was found part way through counting a cell, the entire cell was completed. All sorted organisms were stored in 80% ethanol by family/order in separate labeled vials and debris was preserved and labeled separately. Identifications of all insects to the genus/species level and non-insects to the genus/species level where possible (but to minimum family level) were conducted by experienced, certified taxonomists using standard keys and comparison to an externally-verified reference collection, and effort lists compiled by PNAMP (Pacific Northwest Aquatic Monitoring Partnership). Following identification and counting, representative specimens of each taxon were preserved in 75% ethanol (with 3% glycerol) in a museum quality vial with a polyseal lid to create a voucher collection. The interior labels were used to identify the taxa, the client, date collected, site code and the project.

Laboratory quality assurance/quality control (QA/QC) included an assessment of sub-sampling error and sorting efficiency on at least 10% of the samples (Environment Canada 2002, 2012a). All data were then entered into proprietary software, which was also used to calculate benthic invertebrate community metrics and generate the taxonomic report.

4.5.3 Data Analysis

Benthic invertebrate community data associated with lake environments (Polley Lake, Bootjack Lake and Quesnel Lake) were evaluated using the control-impact study designs summarized in Table 4.1 and benthic invertebrate community data of the Quesnel River were evaluated using a Reference Condition Approach (RCA; Bailey et al. 2004). Benthic invertebrate communities were evaluated using metrics of mean invertebrate density (organisms per m^2; grab samples) or mean abundance (kick-and-sweep samples), mean taxonomic richness, Simpson's Evenness Index (calculated as in Smith and Wilson 1996; Environment Canada 2012) and the Bray-Curtis Index of Dissimilarity (calculated as in Bray and Curtis 1957). These biological endpoints (density, taxon richness, diversity, evenness and community composition) were calculated following the exclusion of Collembola, Ostracods, Cladocera, Copepoda, Malastrocoda because these are pelagic organisms, and Nemata and Turbellaria because these organisms are so small that they are not reliably retained during sieving and can therefore substantially contribute to spatial and/or temporal variability, thereby reducing power to detect general differences in benthic invertebrate community condition. The primary indices were calculated at the lowest practical level of taxonomy. Simpson's Index of Diversity (calculated as in Smith and Wilson 1996; Environment Canada 2012a) was also used to describe benthic invertebrate communities. The relative proportions of the most abundant taxa were also computed (calculated as the abundance of each respective dominant/indicator taxon relative to the total number of organisms in the sample). Dominant/indicator taxon groups were defined as those groups representing more than 5% of total organism abundance or any groups considered to be important indicators of environmental stress. All required and selected endpoints were summarized by reporting mean, median, minimum, maximum, standard deviation, 90% confidence intervals of the mean, and sample size for each sampling site.

Correspondence analysis (CA) was then used to further examine benthic invertebrate community structure. CA is a multivariate technique, which is used to create synthetic species prevalence axes extracted in a sequential manner. Each score (number) on a CA axis is the sum of a weighted vector of species proportion. Species with correlated proportions vary together and will have similar weights and scores on a CA axis. When depicted in two-dimensional plots, taxa that tend to co-occur plot together, while those that rarely co-occur plot farther apart. Similarly, stations sharing many taxa plot closest to one another, while those with little in common plot farthest apart. The greatest variation among either taxa or stations is explained by the first axis, with other axes accounting for progressively less variation. This type of multivariate analysis describes not only which stations have distinct benthic communities but also how these benthic communities differ among stations (i.e., which particular taxa differ). Prior to CA, the data were screened for rare taxa, as these can distort results. Taxa occurring at 5% or fewer of the stations were removed. After screening and data reduction, a proportional data matrix was used to conduct a CA using the program PC-ORD© version 6 (McCune and Mefford 2011). Scores for both taxa and stations were calculated to evaluate the associations of organisms and stations. To ensure that each interpreted axis explained more variation in the dataset than by chance alone ($p<0.05$), a Monte Carlo randomization test was performed using 999 randomized runs of the original dataset (McCune and Grace 2002).

Benthic invertebrate community metrics for all lakes (i.e., all control-impact or multiple control-impact designs) were then plotted, by area, to explore spatial patterns in the benthic community data (the approach to statistical evaluation of the Quesnel River data using the RCA approach is described separately below). Multivariate analysis of variance (MANOVA), followed by analysis of variance (ANOVA) and, as applicable, *post-hoc* Bonferroni comparisons, were used to test for differences in benthic metrics among areas. Data were transformed as necessary to satisfy assumptions of normality and homogeneity of variance. In instances where variances could not be homogenized by transformation, post-hoc tests not requiring this assumption (Tamhane's) were used instead of Bonferroni comparisons. Statistical tests and plots were generated using SPSS version 22 software (IBM Corp. 2013). An effect on the benthic invertebrate community was defined as a statistically significant difference between an event-exposed area and the comparable reference area at an alpha level of 0.10 (Environment Canada 2012a). Interpretation of benthic community metrics was enhanced by inspection of raw data and taxonomic proportions to detect patterns of ecologically relevant differences between reference and exposure areas. Ecological and habitat requirements of benthic invertebrates, as outlined in standard references (Clarke 1981; Edmunds et al. 1976; Weiderholm 1983; Wiggins 1996; Merritt et al. 2008), were used in data interpretation. Lastly, to verify the conclusions derived from the statistically appropriate ANOVA and post-hoc testing, additional pairwise t-testing was conducted and results compared to the ANOVA/post-hoc results. This step essentially asks the question of whether conclusions would differ if the study design were based on simple control-impact comparisons.

In instances when a significant difference between effluent-exposed and reference area means was detected using ANOVA, the magnitude of the difference was calculated for that metric. The Technical Guidance Document (Environment Canada 2012a) states that the benthic invertebrate community survey should minimally have sufficient power to detect a difference (effect size) of ± two standard deviations (SDs). Therefore, the magnitude of the difference was calculated to reflect the number of reference mean SDs as follows:

(exposure mean – reference mean) / SD of the reference mean

If a significant difference between areas was not detected for a benthic metric, then the minimum effect size that could be detected was calculated using the mean square error generated from the ANOVA as an estimate of variability, with alpha and beta equal to 0.10. The minimum detectable effect size was based on the minimum number of reference area standard deviations, according to the following equation:

$\delta = [(t_\alpha+t_\beta)(\sqrt{MSE})(\sqrt{2/n})]/SD_{ref}$, where

δ = minimum detectable effect size,

MSE = mean square error

n = sample size per area (in this case = 5), and

SD_{ref} = standard deviation of the reference mean.

For Polley Lake basins (POL-P1 and POL-P2), historical benthic invertebrate community data were available (HKP 1996, 1997; Beak 2000), and 1999 data (Beak 2000) were of sufficient quality to allow quantitative temporal comparison. The data (Beak 2000) were used to recalculate the metrics described above following the same exclusion rules as above to ensure valid temporal comparison. Metrics for the Polley Lake basins (2014) were then compared to the data from 1999 (Beak 2000) using the same general approach outlined above.

The RCA experimental design (applied to Quesnel River benthic invertebrate community data) evaluates exposed sites against a reference condition, which is composed of multiple reference sites. Therefore, a traditional ANOVA evaluation cannot be used in an RCA design. When testing for statistical differences between exposed sites and multiple reference areas, two non-central tests were employed; a one-sample, non-central, equivalence test; and a one-sample, non-central, interval test (Kilgour et al. 1998).

Determination that a test site is different from the reference condition (i.e. outside the range of reference values) was based on a critical effect size of 1.96 reference standard deviations and tested using two null hypotheses: H_{01} – the absolute value of the reference mean subtract the test site value is ≥ 1.96 reference standard deviations (equivalence test), and H_{02} – the absolute value of the reference mean subtract the test site value is ≤ 1.96 reference standard deviations (interval test). This testing results in three possible outcomes: a non-central p-value (ncP) < 0.1 (interval test) that indicates a community endpoint is outside of the reference condition; a ncP > 0.9 (equivalence test) that indicates a community endpoint is within the reference condition; and a ncP-value between 0.1 and 0.9 that is inconclusive with respect to potential difference from the reference condition (Kilgour et al. 1998). Any exposed stations found to be statistically outside the range of reference conditions (ncP < 0.1) were further evaluated through inspection of the raw data and taxonomic proportions. The ecological and habitat requirements of the dominant taxa were assessed using standard references (Clarke 1981, Edmunds et al. 1976, Weiderholm 1983, Wiggins 1996, Merritt et al. 2008) in order to consider the statistical results of benthic invertebrate community survey in the context of ecological and habitat requirements.

Potential relationships between benthic invertebrate community metrics and physical and chemical conditions of the study areas were explored using correlation analysis as part of causal assessment (Suter et al. 2015). In order to reduce the number of potential correlations considered, benthic invertebrate community metrics were compared to physical variables and to a reduced set of chemical variables (e.g., meter measures, sediment chemistry PCA axes, POIs and selected IPs in lakes; meter measures and water chemistry PCA axes in the Quesnel River). Following derivation of correlation coefficients, a Bonferroni-type correction (i.e., p-value [0.05] divided by the total number of correlations examined for independent variables only) was applied to minimize the risk of declaring false positive correlations since at least 5% of derived correlations would be expected to occur by chance alone at an uncorrected p-value of 0.05. Any significant correlations found at the Bonferroni-adjusted p-value or at a p-value of 0.01 were further investigated using scatter plots to determine if a continuous distribution of data was realized (possible causal relationships) or if these relationships were leveraged by outlying points (or groups of points). The effects of leverage were carefully considered because any difference in benthic community attributes of the effluent-exposed areas relative to reference might be correlated with failure-related differences in water or sediment quality regardless of cause. Significant correlations, coupled with careful examination of scatterplots, were used to identify the factors that most contribute to variability in benthic invertebrate community endpoints. These factors were then considered in light of known physical and chemical influences on benthic invertebrate communities (e.g., stimulation by nutrient enrichment, toxicity by exposure to high metal concentrations).

Benthic invertebrate community data were also integrated with the concurrently collected sediment chemistry and sediment toxicity test data to apply a weight-of-evidence approach (WEA) to interpretation of potential effects of the tailings dam failure on sediment chemistry and aquatic life (i.e., the sediment quality triad; see Section 4.7).

4.6 Benthic Invertebrate Tissue

The objective of benthic tissue collections was to characterize the influence of the tailings dam failure on tissue quality of benthic invertebrates of the Quesnel River. A secondary objective of the sampling is to provide post-event baseline data against which to track potential changes in benthic invertebrate tissue quality over time.

Benthic invertebrate samples for tissue analysis were collected from the Quesnel River and associated reference sites (Table 2.1). Reference sites included the Cariboo River, the Clearwater River, and the Blackwater River (Figure 4.6). Benthic invertebrate tissue samples were collected concurrent with, and at the same location as, benthic invertebrate community samples.

4.6.1 Sample Collection

At each site, two benthic invertebrate tissue samples were collected, one a composite of the entire benthic community and the second a composite of the Plecopteran (stonefly) family Perlidae (often referred to as golden stones). Perlidae were chosen because they are easily identifiable in the field, were estimated to be present and in large numbers at most areas, and having a single taxon provides some standardization across areas that address concerns often raised when amalgamating whole community tissue samples.

Samples of the entire benthic community were collected by kick-and-sweep as described above (Section 4.5.1), with the exception that collection was not timed as the objective was simply to collect sufficient tissue for chemical analysis. Samples of Perlidae were obtained by removing cobble from the streambed and inspecting their undersides for organisms. In both cases, sampling was continued until the required 200 mg of sample was attained (required for the effective analytical determination of analytes of interest. To ensure that invertebrate picking was not biased toward large mobile organisms the whole sample was sorted. If the total tissue collected did not exceed the minimum 200 mg necessary for laboratory measurements additional kick samples were collected. Specific effort was made to target similar habitats for collection of both community and tissue samples within each area. Once the tissue sample was collected, organisms were picked free of debris in the field, placed into a labelled 30-mL (1-oz) Whirl-Pak® bag and stored in a cooler with ice packs until transferred to a freezer later the same day. Frozen samples were shipped by courier in coolers with ice packs to SRC (Saskatchewan Research Council) Analytical Laboratories.

4.6.2 Laboratory Analysis

Upon receipt, SRC opened the cooler(s), measured temperature to verify the maintenance of cold samples, removed each sample from the cooler(s), logged the sample, and assigned each sample a unique sample identification code. Laboratory analysis included freeze-drying and determination of total metals using ICP (inductively coupled plasma). Results were reported on a dry-weight basis, along with moisture content to allow future conversion of results to a wet-weight basis, if required.

4.6.3 Data Analysis

Metal concentrations in composite samples of the whole benthic invertebrate community and in composite samples of Perlidae only (golden stoneflies) were assessed by ANOVA with post-hoc contrasts as described in Section 4.5.3. In addition, metal composition gradients determined through PCA were examined to describe spatial differences/patterns.

4.7 Data Integration

Beyond the interpretation of individual components of the sediment quality impact characterization, it is critical that relationships among the components are characterized and considered, and data are applied in a weight-of-evidence approach (WEA). The objective of data integration is to use all available data to define chemical and biological impact.

In data integration, relationships among components of the monitoring plan were specifically explored to determine which analytes consistently emerge as evidence of impact and to characterize relationships among endpoints to determine biological effects and their probable cause. The key tool for this examination, as outlined in the sediment toxicity section (Section 4.4.3) and in the benthic invertebrate community section (Section 4.5.3), is correlation analysis. Throughout this report, a weight of evidence is built by adding layers of information (e.g., sediment quality is considered in light of water quality; benthic invertebrate community condition is considered in light of water quality, sediment quality, toxicity test results and physical conditions) to identify relationships and concordance.

Relationships among program components were also explored by compiling the results of the different monitoring components in a table and examining concordance of effects. This WEA evaluation is a collective evaluation of all pertinent information so that the full spectrum of information is adequately considered (USEPA 2004). The concordance table was used to identify locations that were clearly impacted, those that were clearly un-impacted (or mildly impacted), and those for which the evidence is equivocal in order to communicate magnitude and extent of impact.

5.0 HAZELTINE CREEK

Sediment quality impact characterization in Hazeltine Creek included sediment chemistry, sediment geochemical characterization and sediment toxicity testing (Table 4.1; Figure 4.2). Benthic invertebrate community samples were not collected in Hazeltine Creek due to the absence of appropriate erosional habitat post-event (i.e., substrates were entirely fine materials derived from the tailings pond and scoured creek bed). As the geomorphology of Hazeltine Creek stabilizes and typical erosional habitat (cobble and gravel) becomes available (i.e., exposed by hydrological/geomorphological processes), benthic invertebrate community recovery will be monitored.

Data Quality Assessment (DQA; Appendix C with supporting data in Appendix J) indicated that sediment quality data and toxicity test results were of good quality and can therefore be used in the sediment quality impact characterization.

5.1 Sediment Physical and Chemical Characterization

Substrates of Hazeltine Creek were observed to be composed primarily of two types of sediment: orange and black sand and grey fines. The same categories were previously reported (SRK 2014), with the former (orange and black sand) being dominated by plagioclase feldspar and magnetite and the latter (grey fines) being dominated by potassium feldspar and plagioclase, with minor biotite mica and quartz (SRK 2014, 2015). Substrates at the three sampling areas in Hazeltine Creek were predominantly sand and silt (Table 5.1; Appendix Table E.1). Substrate at the uppermost area (ST16) was somewhat more coarse (approximately 70% sand and 30% silt) than substrates at the mid- (ST09) and lower (ST02) areas (approximately 20-30% sand and 60-70% silt; Table 5.1). Total organic carbon (TOC) content of all sediment samples was low (<0.2%).

Arsenic, copper, iron and nickel were the only analytes with concentrations in Hazeltine Creek sediment greater than working sediment quality guidelines for the protection of aquatic life (probable effect levels [PELs] in the case of copper and iron and threshold effect levels [TELs] in the case of arsenic and nickel) and pre-event concentrations (Tables 5.1 and 5.2; Figure 5.1). Both arsenic and nickel were elevated above reference only in the <63 µm sediment (compared to historical results based on bulk sediment) at one of three areas only (Table 5.2). Concentrations of eight additional analytes were present in Hazeltine Creek sediment at concentrations more twice pre-event concentrations (calcium, cobalt, molybdenum, phosphorus, silver, sodium, titanium and vanadium; Tables 5.3 and 5.4; Figure 5.2). In accordance with the framework set out in Section 4.0, arsenic, copper, iron and nickel are designated as Parameters of Interest

Table 5.1: Summary of sediment quality data for Hazeltine Creek, Mount Polley Mine, 2014. Metals data are based on the <2mm fraction of sediment[1].

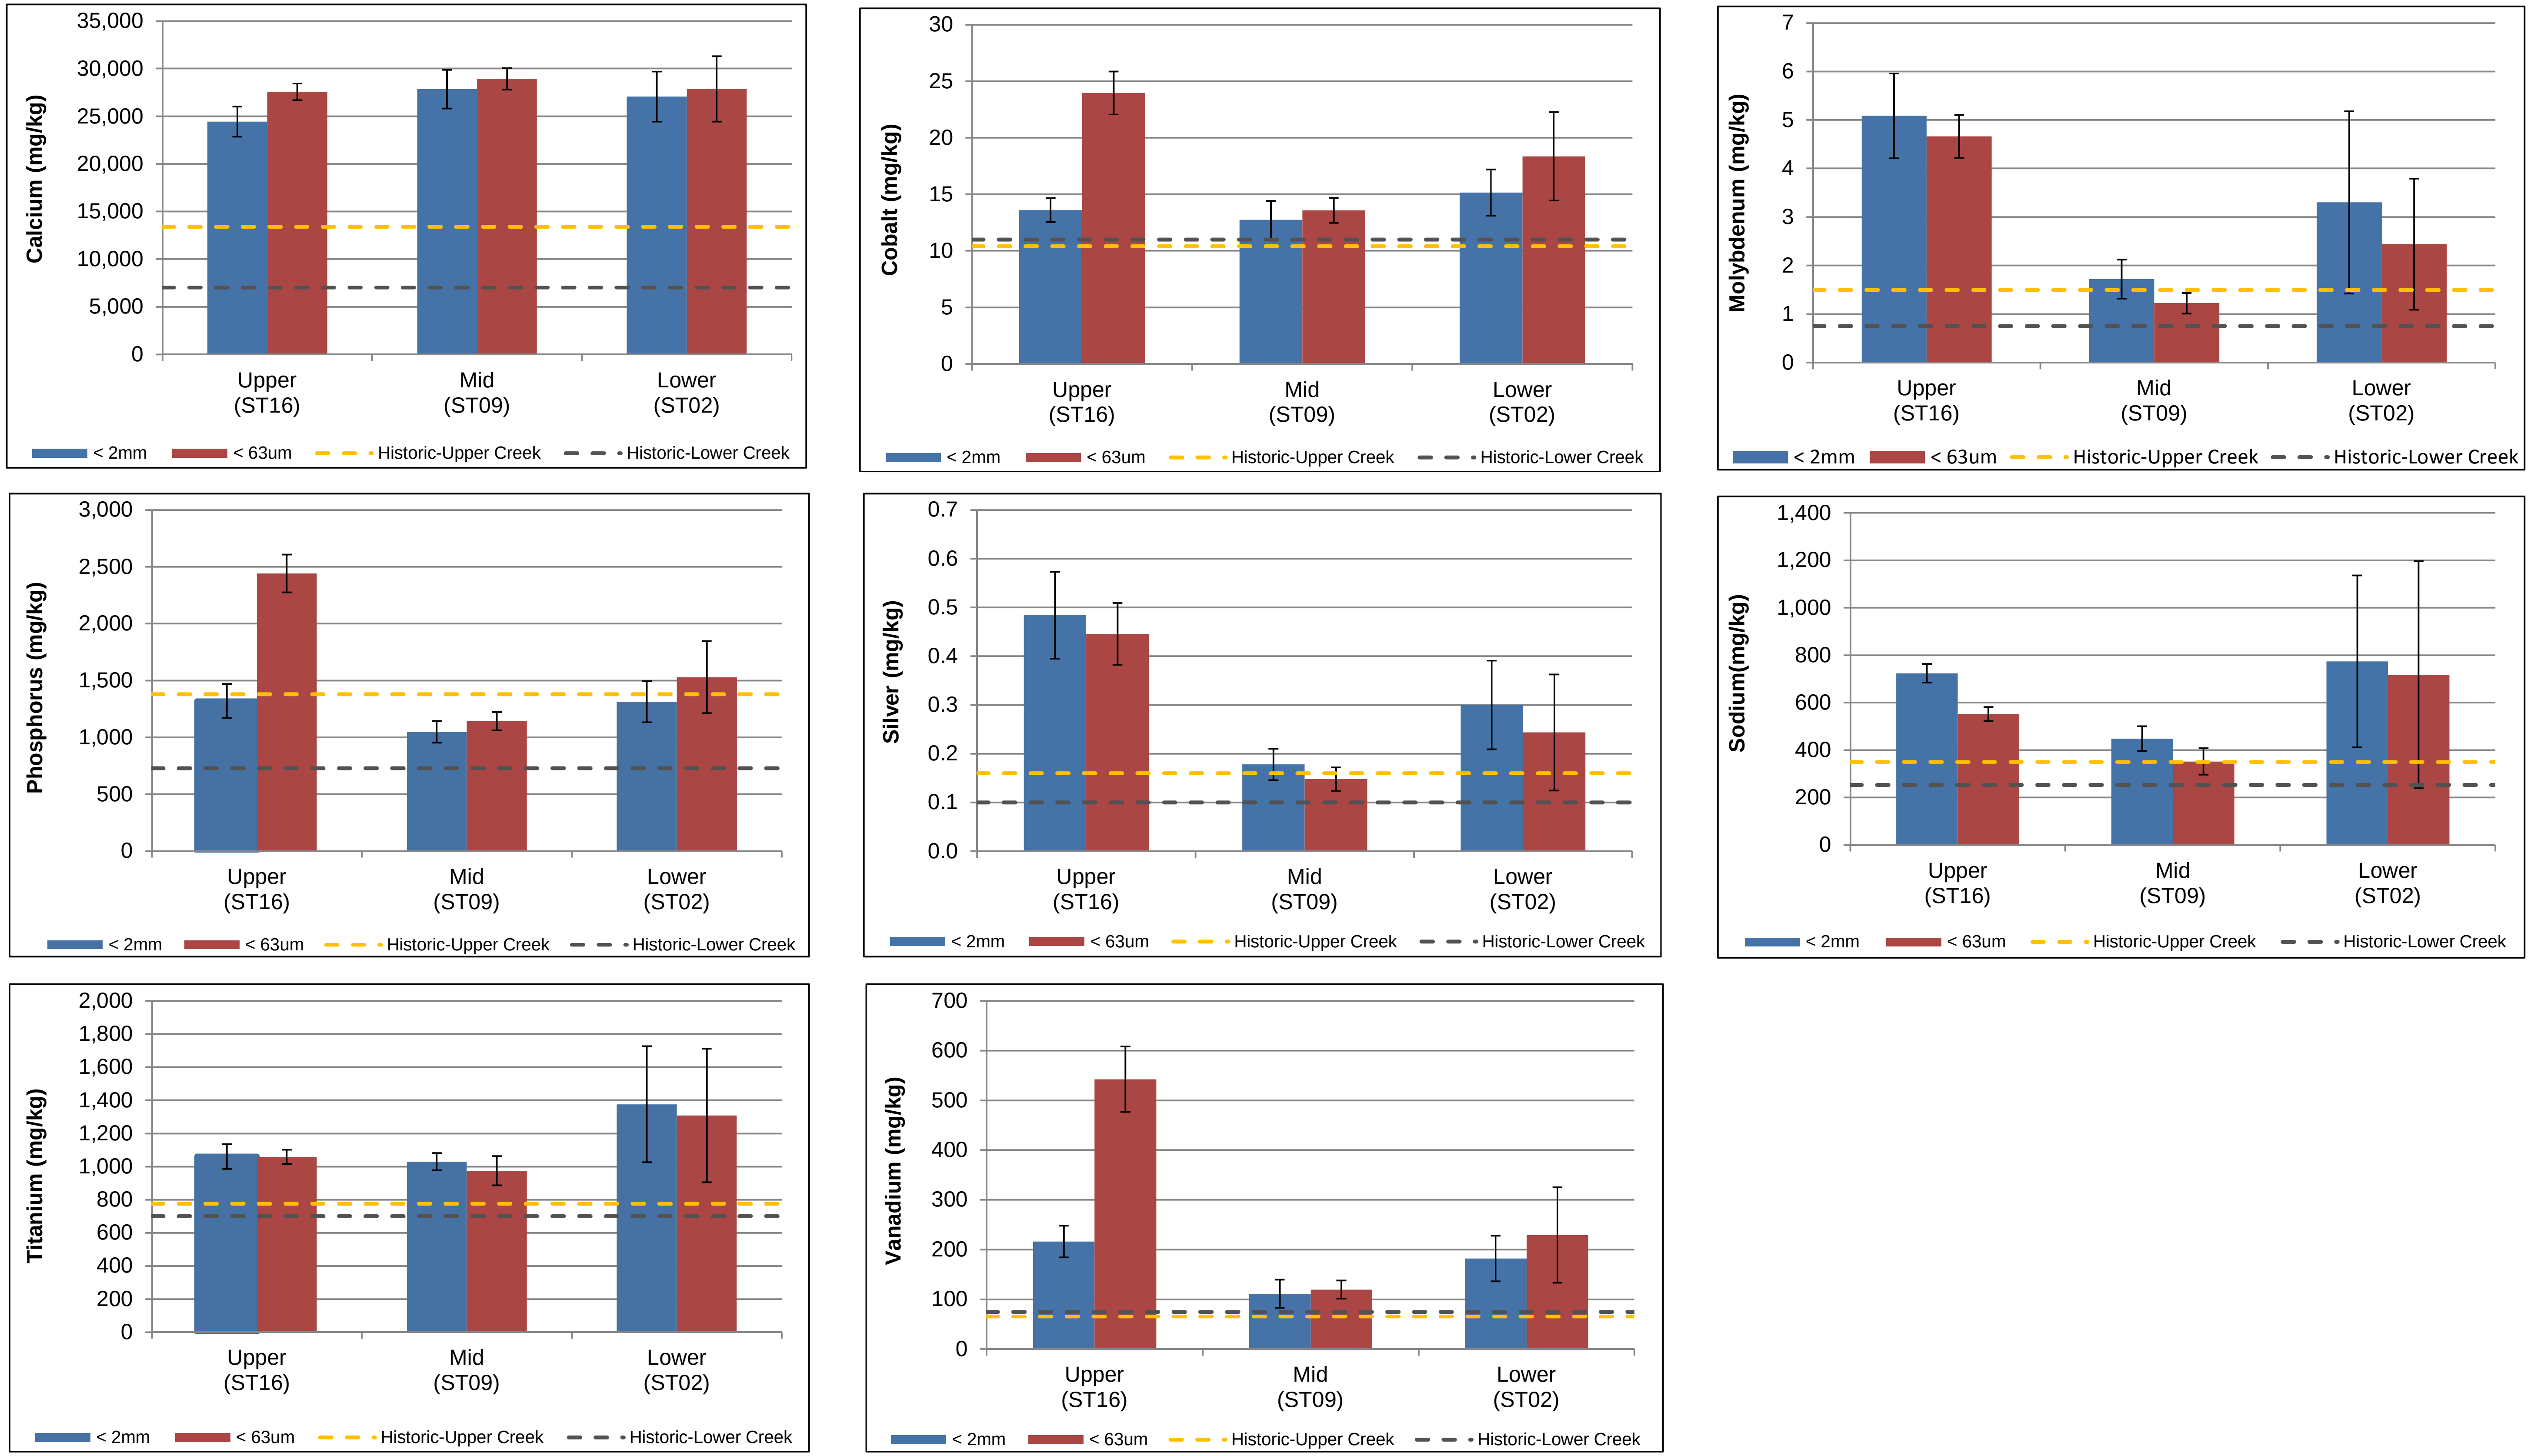

Figure 5.2: Mean metal concentrations (± t*SE) for indicator parameters in sediment from Hazeltine Creek sampling areas, Mount Polley Mine, 2014.

Historic = Historic 95th percentile for either upper or lower Hazeltine Creek areas. Historic data are based predominantly on bulk sediment.

(POIs) and calcium, cobalt, molybdenum, phosphorus, silver, sodium, titanium and vanadium are designated as Indicator Parameters (IPs).

Principal Components Analysis (PCA) was effective in distinguishing the sediments of area ST16 (upstream) from area ST09 (mid) and some ST02 (downstream) stations primarily on the basis of higher percent sand/lower percent fines, lower TOC content, and higher concentrations of a number of metals (arsenic, beryllium, copper, iron, mercury, molybdenum, phosphorus, selenium, silver and sodium; Figure 5.3). With the exception of calcium, cobalt, nickel, titanium and vanadium, this list includes all POIs and IPs identified above and serves to confirm their designations.

Of the four POIs and eight IPs, copper was the most substantially elevated, with mean concentrations up to approximately five times the PEL and fifteen times pre-event concentrations (Tables 5.1 to 5.4; Figures 5.1 and 5.2). Copper concentration was greatest at area ST16 (upstream) and, unlike the other POIs, was enriched in <2 mm fraction relative to <63 µm fraction (Figure 5.1). Iron was also elevated relative to the PEL, but to a much lower mean magnitude (up to approximately 1.3 times in the <2.0 mm fraction and 3.2 times in the <63 µm fraction) and up to approximately 2.1-times background and 5.3-times background in the <2.0 mm and <63 µm fraction, respectively (Tables 5.1 to 5.4; Figure 5.1). Iron was notably elevated in the fines at area ST16 (upstream; 5.3-times; Table 5.4), where concentration in the <63 µm fraction was more than double that in the <2.0 mm fraction (Figure 5.1). As indicated above, mean concentrations of arsenic and nickel only exceeded reference in the <63 µm sediment (compared to historical results based on bulk sediment) at one of three areas only (arsenic at ST16 [upstream] and nickel and ST09 [mid-stream]).

Of the IPs, concentrations of calcium, cobalt, phosphorus, and vanadium were generally higher in the <63 µm sediment than in the <2.0 mm sediment, whereas the opposite was true of molybdenum, silver, sodium and titanium (Figure 5.2).

Concentrations of copper, molybdenum, silver and vanadium were all negatively correlated with percent fines (percent silt and clay), whereas concentrations of nickel and calcium were positively correlated with percent fines (Table 5.5; Appendix Figure E.1). Similarly, concentrations of arsenic, copper, iron, molybdenum, phosphorus, silver, sodium and vanadium were negatively correlated with sediment total organic carbon (TOC) content and concentrations of nickel were positively correlated with TOC, despite the fact that TOC content was low and spanned a very narrow range from <0.10 to 0.20 % (Table 5.5; Appendix Tables E.1-E.2; Appendix Figure E.2). Overall, these relationships indicate that concentrations of most POIs and IPs (with the exceptions of calcium and

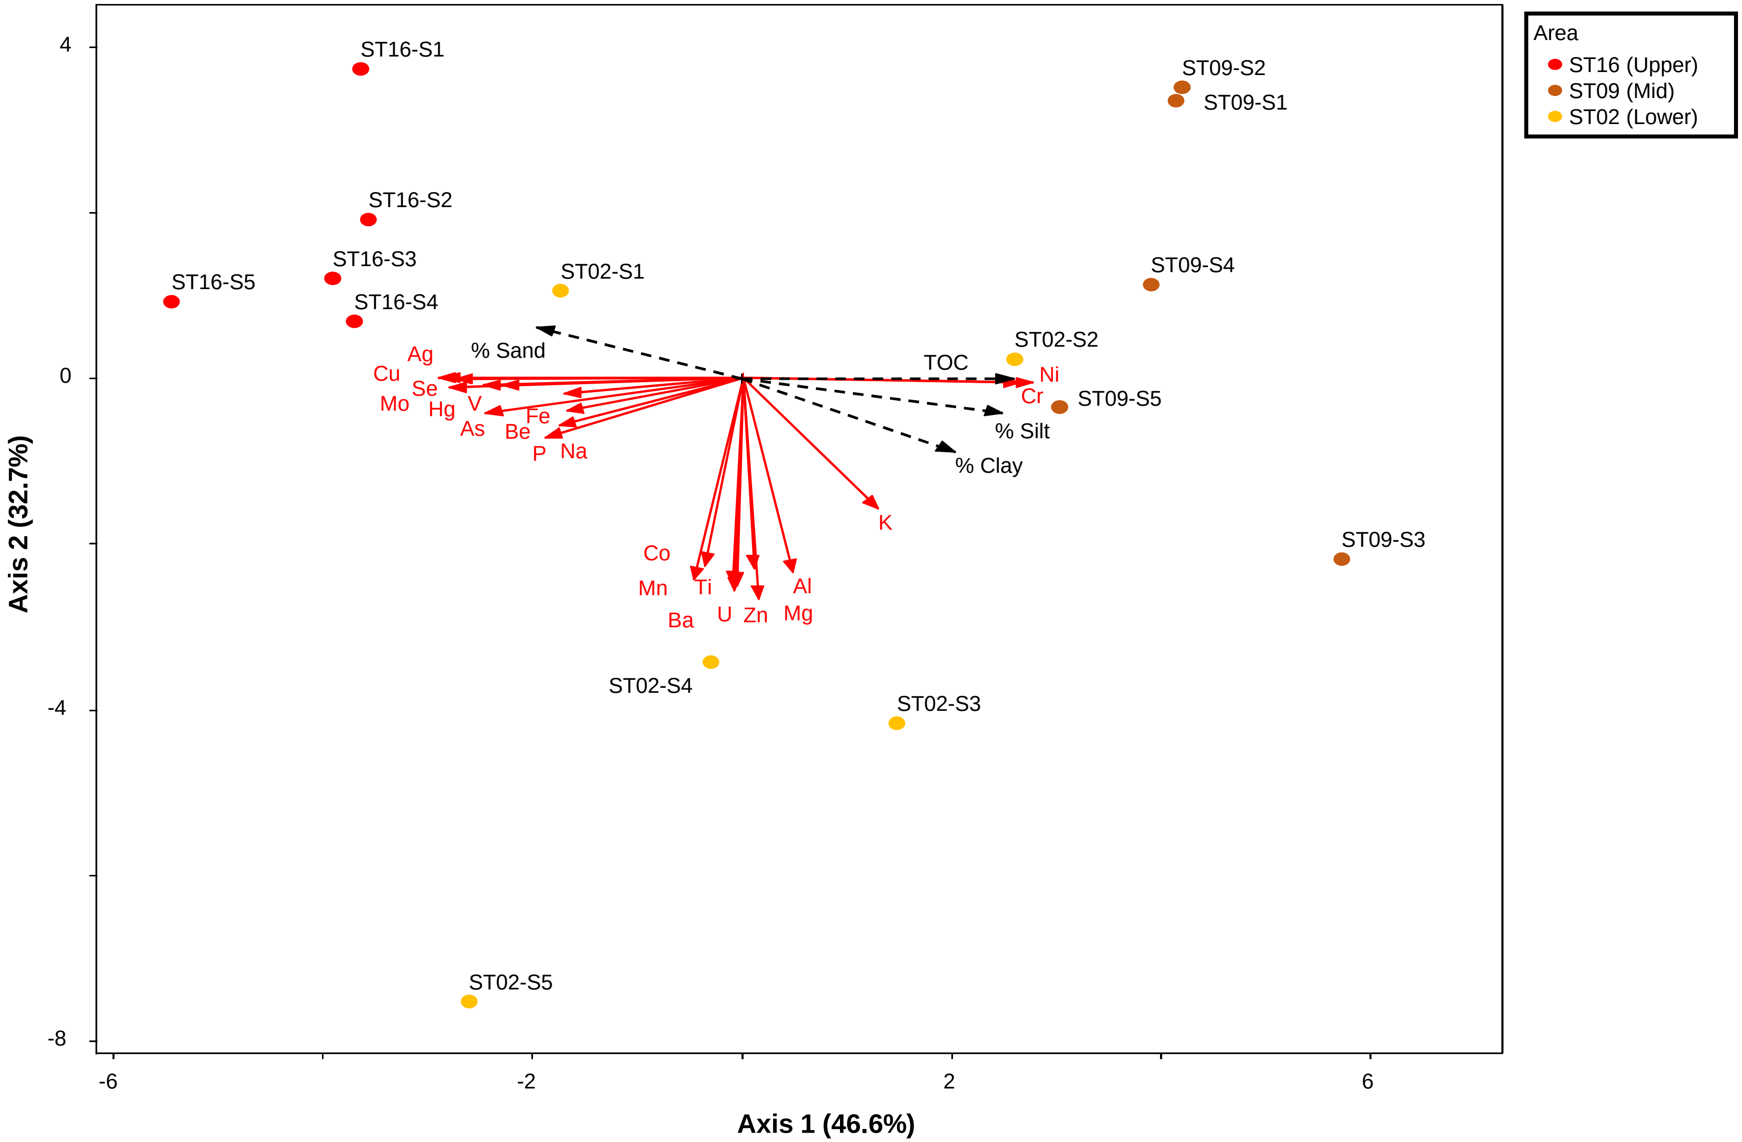

Figure 5.3: Biplot of principal component analysis (PCA) of metal concentrations in sediment (<2 mm fraction) from Hazeltine Creek sampling stations, Mount Polley Mine, 2014. Vector length is proportional to the magnitude of direct correlation of metals (solid red vector lines) and indirect correlation of sediment physical characteristics (black dashed vector lines) with PCA values of each axis (Appendix Tables E.3-E.4). Only metals with significant (p-value <0.010) Spearman's correlation and r-values > 0.7 with either axis are displayed, all sediment physical characteristics are displayed [a].

[a] Boron and tin were excluded from calculations due to a lack of variability in the data (all values for each analyte were the same).

Table 5.5: Spearman's Rank Correlation results for correlation of concentrations of parameters of interest and indicator parameters (in < 2mm sediment fraction) relative to % fines (silt and clay) and total organic carbon in sediment from Hazeltine Creek sampling areas, Mount Polley Mine, 2014 [1].

Note: n=15 for all correlations.

nickel) are associated with sandy, low TOC sediment, which is consistent with event-derived materials (i.e., tailings and scoured Hazeltine channel). The negative relationships with particle size and TOC for most POIs and IPs indicates that the dominant process influencing sediment concentrations of these analytes are primary the chemistry of the source material rather than secondary sorptive processes in the receiving environment.

5.2 Sediment Geochemical Characterization

There are numerous factors that affect the bioavailability of sediment-associated metals. While metal concentrations that are below sediment quality guidelines generally provide a reliable indicator of an absence of effect, sediment quality results that exceed those benchmarks provide a less reliable indication that effects are probable. Geochemical characterization can assist in identifying the potential mobility and bioavailability of metals associated with mine-influenced sediments.

Selective extractions indicated that concentrations of most POIs and IPs were primarily in the residual phase; that is, they could only be extracted by the strongest acid digest (a combination of concentrated nitric and hydrochloric acid; Table 5.6; Figure 5.4; Appendix Table E.7; Appendix Figures E.4-E.5). Residual metals are unlikely to be mobilized under any conditions that could realistically occur in Hazeltine Creek, nor in interactions with aquatic organisms (i.e., contact with the gill or ingestion) and are therefore considered not biologically available (e.g., Tessier et al. 1979; Campbell and Tessier 1996). Exceptions included calcium, which was predominantly in the carbonate phase (as expected), and copper, which was predominantly in the “organic” phase” (Figure 5.4). However, as there was very little organic matter in the Hazeltine Creek sediments, it is unlikely that this pool of copper was actually organic bound, and there is literature-based evidence that the “organic” fraction can include oxalates which can be formed by the peroxidation of clays (e.g., Farmer and Mitchell 1963) and can be partially broken down in peroxide digests (Gleyzes 2002). In addition, Tessier et al. (1979) observed some alteration of smectite, chlorite and mica minerals (silicates, often alumino-silicates) in the organic digestion (which uses nitric acid, hydrogen peroxide and ammonium acetate; Table 4.5).

Concentrations of copper in selective extraction fractions 1 to 3 (exchangeable + carbonate bound + reducible) alone approached pre-event concentrations (Figure 5.4). However, separate integrated consideration of mineralogy, sequential extraction results and mineral solubility indicates that these forms would not be mobile under environmentally realistic conditions (SRK 2015). This interpretation is being tested by on-going laboratory weathering tests of the Hazeltine Creek sediments (i.e., humidity cell

Table 5.6: Summary of selectively extracted (Tessier extraction) metals data for sediment from Hazeltine Creek, Mount Polley Mine, 2014. Data are based on < 2mm fraction of sediment [1]. Only analytes with detectable concentrations are displayed.

(blue) Value is > TEL. Values shown in bold text also exceed both upper and lower Hazeltine Creek Historic 95th Percentile values.

(orange) Value is > PEL. Values shown in bold text also exceed both upper and lower Hazeltine Creek Historic 95th Percentile values.

[1] Data < method detection limit (< MDL) were used at the MDL for the calculation of summary statistics. Means are reported as < the highest displayed MDL if all the data used in their calculation were < MDL.

[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a; BCMOE 2015b); TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.

[3] Historic sediment metal concentrations are based predominantly on bulk sediment samples.

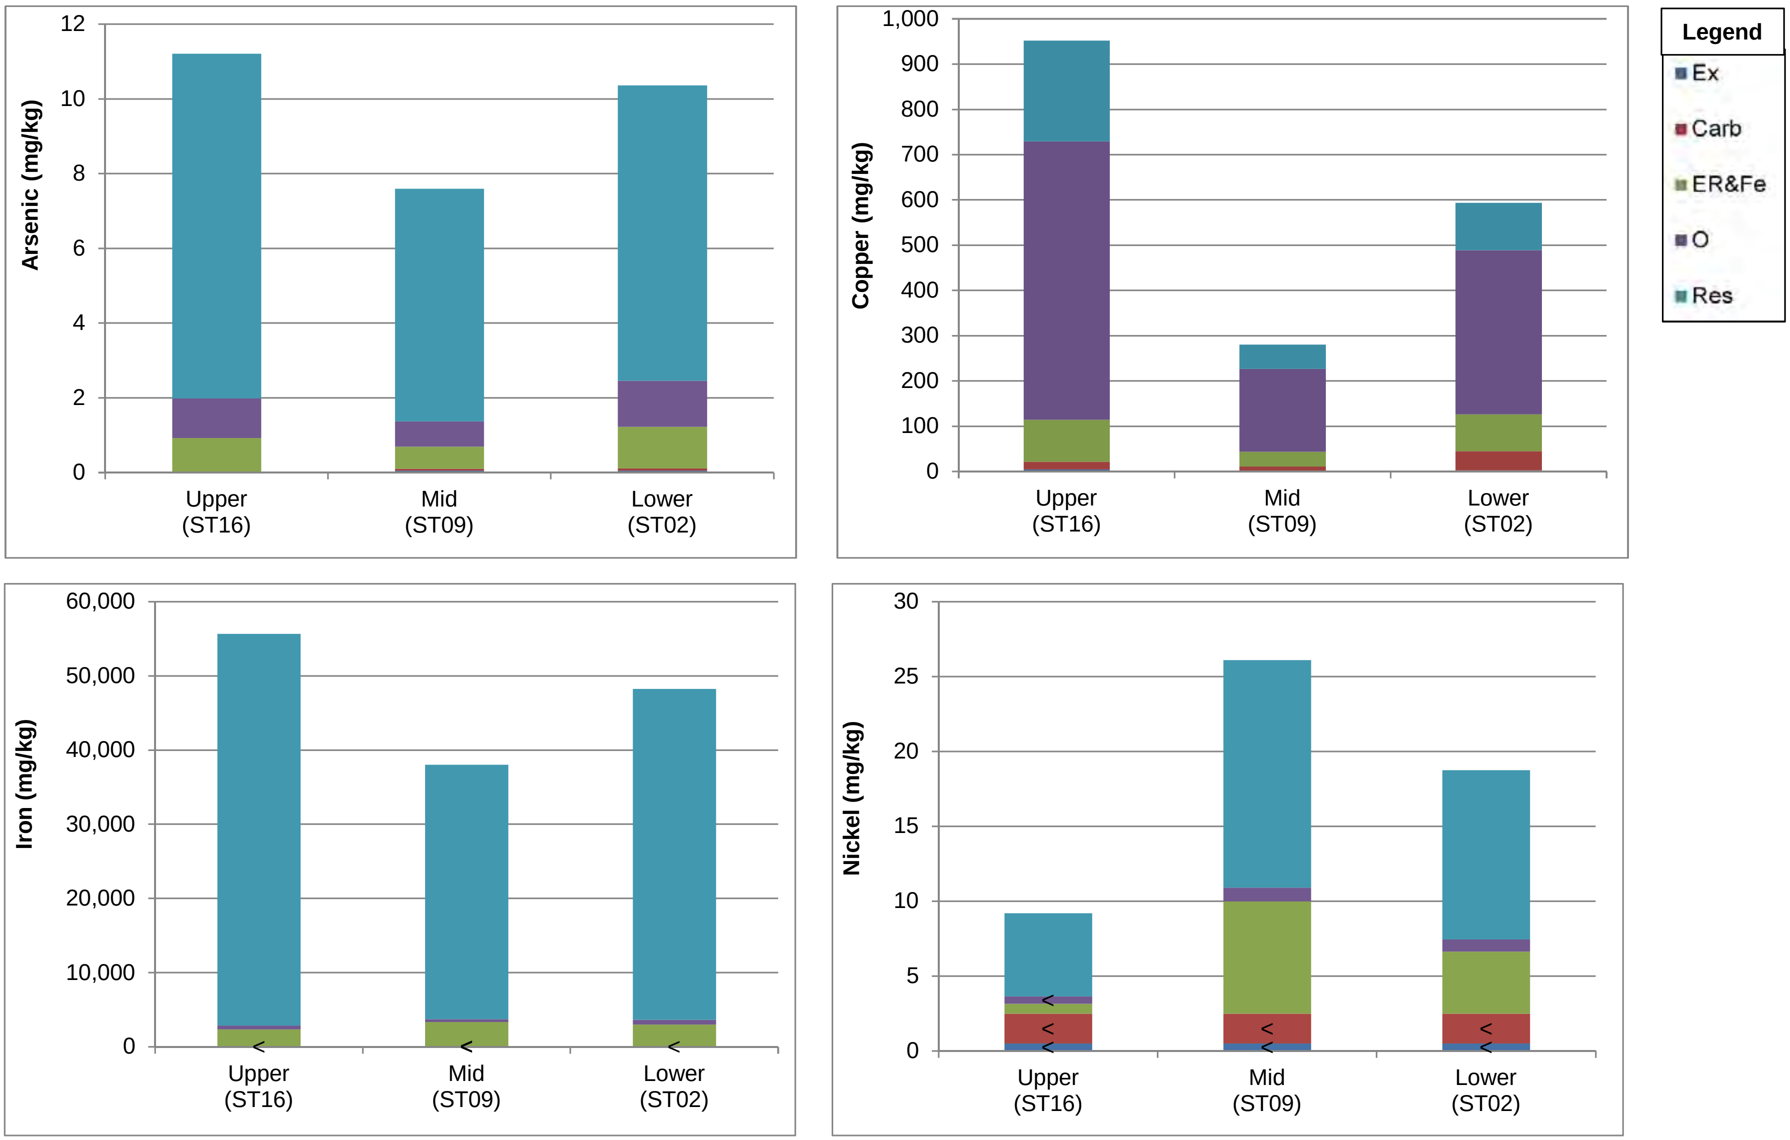

Figure 5.4: Mean concentrations of selectively extracted parameters of interest in sediment from Hazeltine Creek sampling areas, Mount Polley Mine, 2014. Selective extractions included Exchangeable & Adsorbed Metals (Ex), Carbonate Metals (Carb), Easily Reducible Metals and Iron Oxides (ER&Fe), Organic Bound Metals (O), and Residual Metals (Res).

Mean values < MDL are indicated with a < symbol. Means are reported as < MDL if all data used in their calculation were < MDL.

kinetic testing). Therefore, sediment copper also appears to be present in Hazeltine Creek sediments in forms that are not mobile and this immobility suggests limited concern for aquatic biota.

Shake flask tests and porewater chemistry indicated low mobility of metals associated with Hazeltine Creek sediments, with copper being the only metal mobilized in shake flask tests and present in sediment porewater at concentrations greater than British Columbia Water Quality Guidelines (BCWQG; Tables 5.7 and 5.8; Appendix Tables E.8 and E.9). BCWQG do not apply to sediment porewater, but are used herein as an indication of low mobility. The mean concentration of porewater selenium at one area only (ST16, upper Hazeltine Creek) was slightly greater than the BCWQG (0.0025 mg/L vs. guideline of 0.002 mg/L; Table 5.8).

Acid-Base accounting results indicated no potential for acid generation in the Hazeltine Creek sediments (Appendix Tables E.11-E.12). Mean neutralization potential ratio (NPR; the ratio of neutralization potential to maximum potential acidity) ranged from 4.9 at area ST16 (upstream) to 19 at area ST09 (mid-stream). NPR greater than 4 indicates no potential for Acid Rock Drainage (ARD; Price 1997). High NPR in Hazeltine Creek sediment is consistent with high NPR observed in tailings (SRK 2014, 2015). Lower NPR downstream suggests that the NPR of mine tailings may be greater than that of the scoured Hazeltine Creek bed material.

Examination of metal concentrations in four different particle size categories in a large sample collected from lower Hazeltine Creek (at HAC50; Figure 4.2) indicated that concentrations of POIs and IPs were generally similar among size fractions (Table 5.9; Figures 5.5 and 5.6). A pattern of slightly increasing concentrations with decreasing particle size was evident for most analytes; however copper was an exception, with higher concentrations in the sand fraction (Figure 5.5). These subtle patterns have some implications to the dispersion of metals in Quesnel Lake as fine particles are expected to have travelled further downstream. Examination of selective extraction results (Appendix Table E.13 and Appendix Figures E.6-E.7) and shake flask results (Appendix Table E.14) for this sample indicated similar partitioning as observed at areas ST16, ST09 and ST02, and also indicated that copper was the only metal mobilized in shake flask testing to a concentration greater than a BCWQG. Shake flask results indicated greater copper mobility associated with fine sediments than coarse sediments, which is consistent with higher concentrations of easily reducible and “organic” copper in fine sediments (Appendix Figures E.6-E.7)

Table 5.7: Summary of leachable (Shakeflask) metals data for sediment from Hazeltine Creek sampling areas, Mount Polley Mine, 2014. Data are based on bulk sediment [1]. Only analytes with detectable concentrations are displayed.

(orange) Value is > one or all guidelines (values < MDL excluded from comparison).

[1] Data < method detection limit (< MDL) were used at the MDL for the calculation of summary statistics. Means are reported as < highest MDL if all the data used in their calculation were < MDL.

[2] British Columbia Water Quality Guidelines (BCMOE 2015a; BCMOE 2015b); W=Working guideline; A=Approved guideline. See Appendix Table E.10 for derivation of hardness-based guidelines.

[3] Insufficient porewater volume to analyse total or dissolved metals in sample ST16-04 or to analyse total metal concentrations in samples ST16-S2, ST16-S3 or ST16-S5. Total metal concentrations are based only on the result from one sample (ST16-S1) as a result.

[4] Displayed guideline value is for dissolved cadium.

[5] Applies to chromium as Cr (IV); guideline for Cr(III) is 0.0089 mg/L.

[6] Total nickel guideline value is for acute exposure, as described in guideline document (CCREM 1987)

(blue)	Value is > TEL. Values shown in bold text also exceed both upper and lower Hazeltine Creek Historic 95th Percentile values.
(orange)	Value is > PEL. Values shown in bold text also exceed both upper and lower Hazeltine Creek Historic 95th Percentile values.

[1] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a; BCMOE 2015b); TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.

[2] Historic sediment metal concentrations are based predominantly on bulk sediment samples.

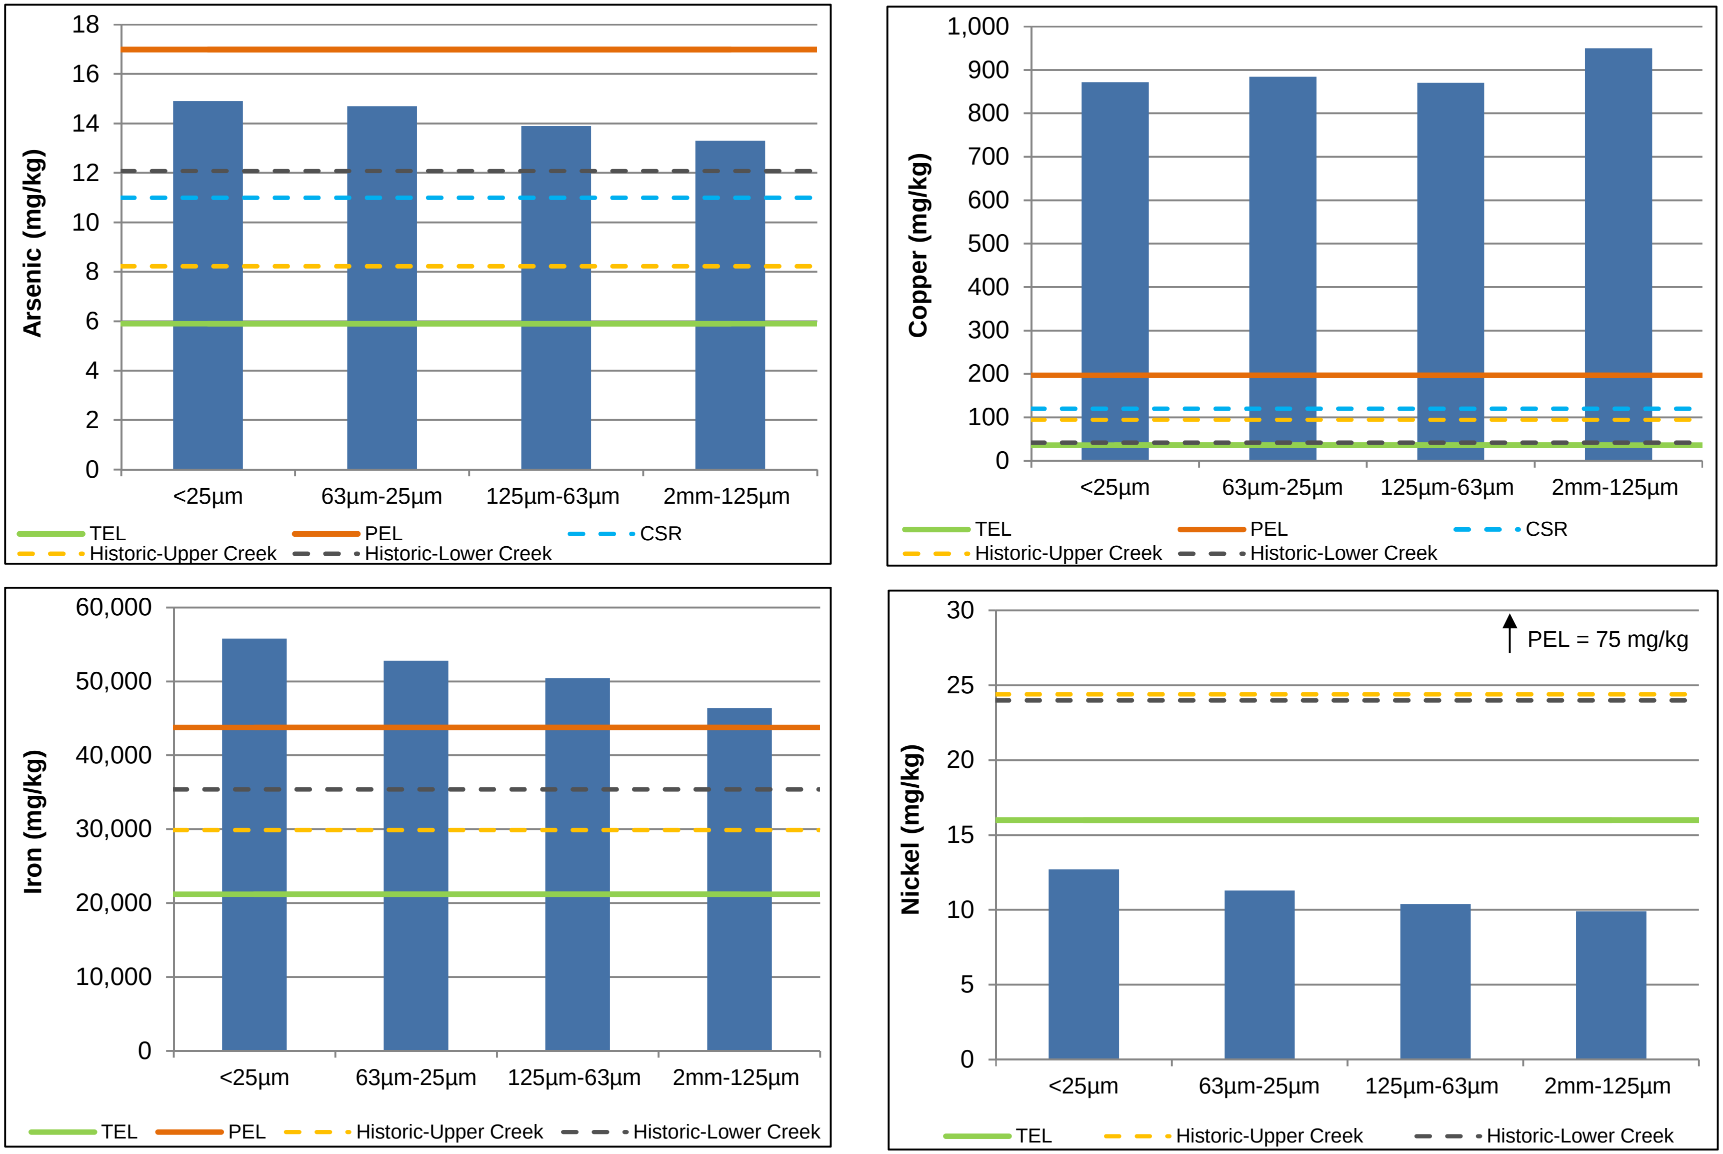

Figure 5.5: Metal concentrations for parameters of interest in Hazeltine Creek size-fractioned sediment sample HAC50, Mount Polley Mine, 2014. Fractions include sand (2mm-125 µm), very fine sand (125-63 µm), medium coarse silt (63-25 µm), and fine silt and clay (<25µm).

TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level; CSR = Contaminated Sites Regulation - Sensitive; Historic = Historic 95th percentile for either upper or lower Hazeltine Creek areas. Historic data are based predominantly on bulk sediment.

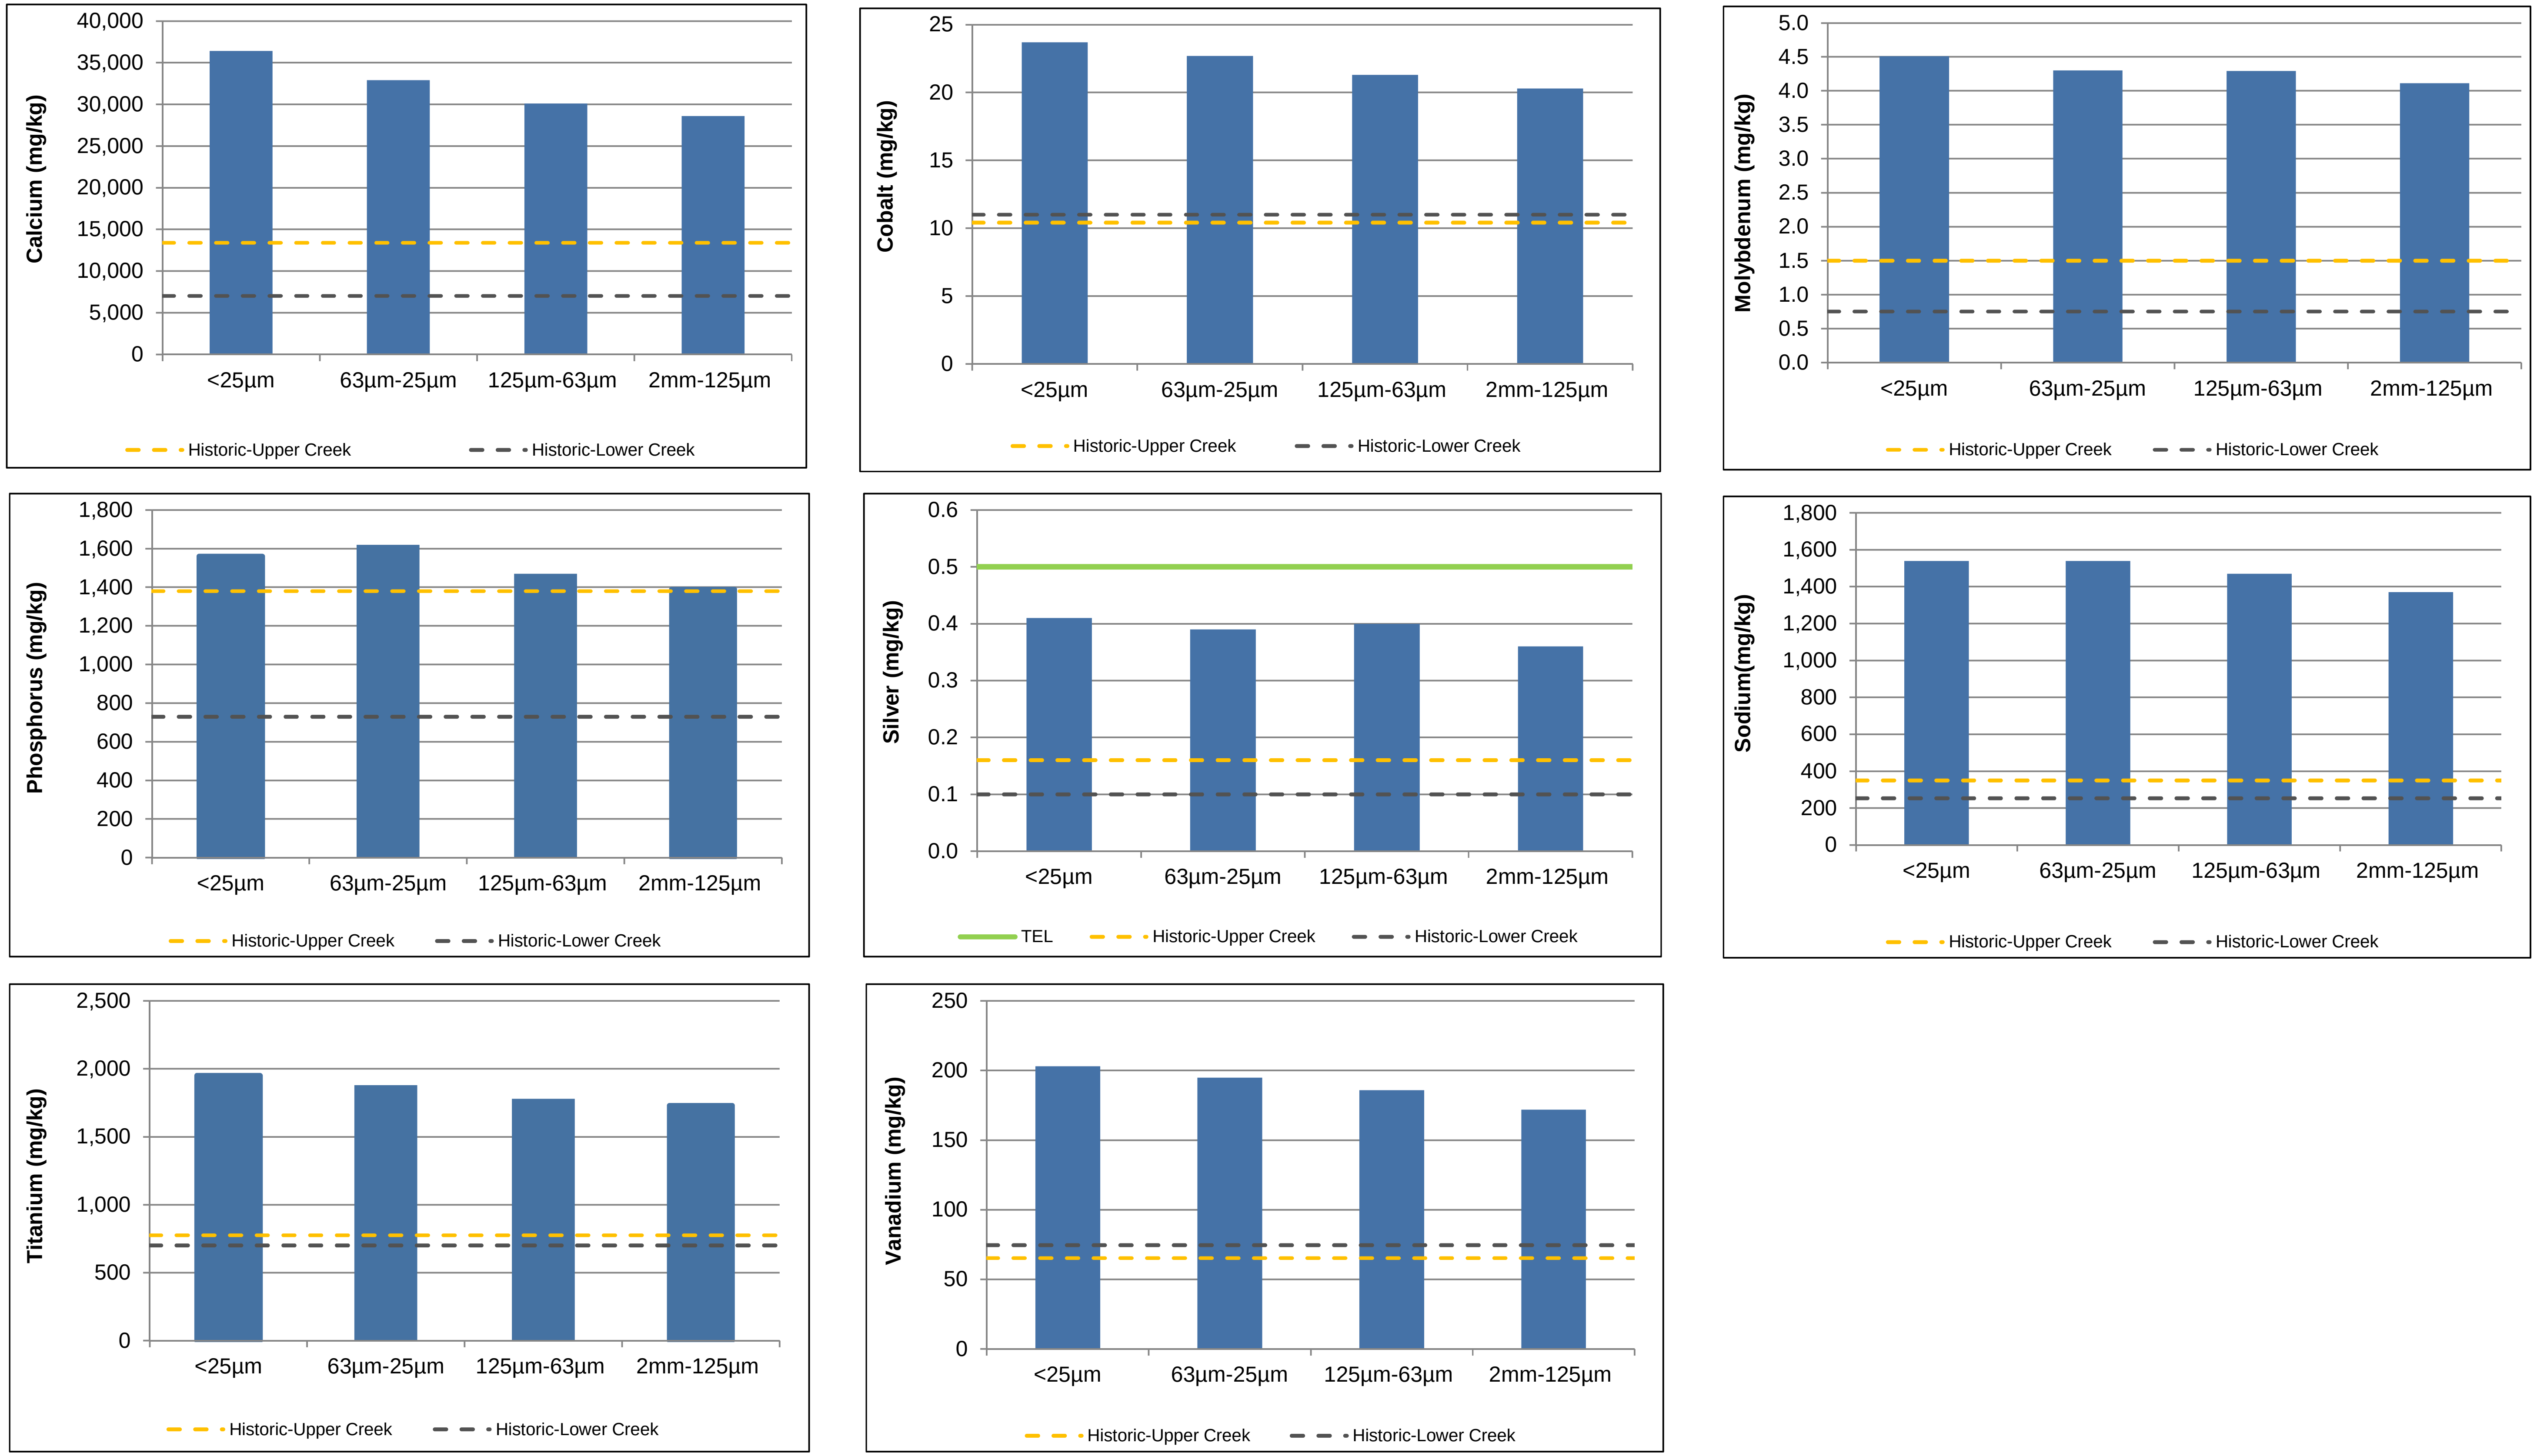

Figure 5.6: Metal concentrations for indicator parameters in Hazeltine Creek size-fractioned sediment sample HAC50, Mount Polley Mine, 2014. Fractions include sand (2mm-125 µm), very fine sand (125-63 µm), medium coarse silt (63-25 µm), and fine silt and clay (<25µm).

TEL = Threshold (or Lowest) Effect Level; Historic = Historic 95th percentile for either upper or lower Hazeltine Creek areas. Historic data are based predominantly on bulk sediment.

5.3 Sediment Toxicity

Sediment toxicity testing indicated significantly reduced survival and growth of the freshwater/brackish water amphipod *Hyalella azteca* at two of four areas within Hazeltine Creek - ST16 (upper) and HAC50 (lower; Figure 5.7; Appendix Table F.1). Survival and growth of *H. azteca* were particularly low at upper Hazeltine Creek (23% and 8% of laboratory control, respectively; Appendix Table F.2), in apparent association with coarser sediment characterized by highest copper concentration (Section 5.1). Conversely, both survival and growth of *H. azteca* at areas ST09 (middle Hazeltine Creek) and ST02 (lower Hazeltine Creek) did not differ from laboratory controls (Figure 5.7; Appendix Table F.1). Survival of the freshwater midge *Chironomus dilutus* was significantly reduced relative to concurrent laboratory controls throughout Hazeltine Creek (40 to 80% of control survival; Figure 5.7; Appendix Tables F.1-F.2). Growth of *C. dilutus* was not adversely affected in samples collected at ST16 (upper Hazeltine Creek), ST09 (middle Hazeltine Creek) or ST02 (lower Hazeltine Creek), but was significantly reduced in sediment collected from station HAC50 (also lower Hazeltine Creek; growth 63% of control; Figure 5.7; Appendix Tables F.1-F.2).

Correlation analysis was conducted between the sediment toxicity test endpoints and percent fines, TOC content, concentrations of POIs, IPs, PCA axes and selective copper extracts. There were no significant relationships between *C. dilutus* survival or growth and any sediment physical or chemical parameters at the Bonferroni-adjusted p-level (Table 5.10). A few negative associations between *C. dilutus* survival and growth and POIs and IPs were evident at $p<0.01$ (Table 5.10). Survival of *H. azteca* was positively correlated with percent fines and calcium at the Bonferroni-adjusted p-level (Table 5.10; Appendix Figure I.1). A number of negative associations between *H. azteca* survival or growth and POIs and IPs (including exchangeable and organic copper) were evident at $p<0.01$ (Table 5.10; Appendix Figure I.2). Although correlation does not necessarily indicate causation, the positive relationships with percent TOC and PCA axis 1 (lower concentrations of POIs and IPs) and the negative relationships with arsenic, copper, iron, molybdenum, silver, vanadium, exchangeable copper and organic copper represent plausible mechanisms of biological effect.

5.4 Benthic Invertebrate Community

No benthic invertebrate community sampling was conducted in Hazeltine Creek in 2014 due to the absence of appropriate erosional habitat post-event (i.e., substrates were entirely fine materials derived from the tailings pond and scoured creek bed). Benthic invertebrate sampling will be undertaken in the future (starting in 2015) to track recovery

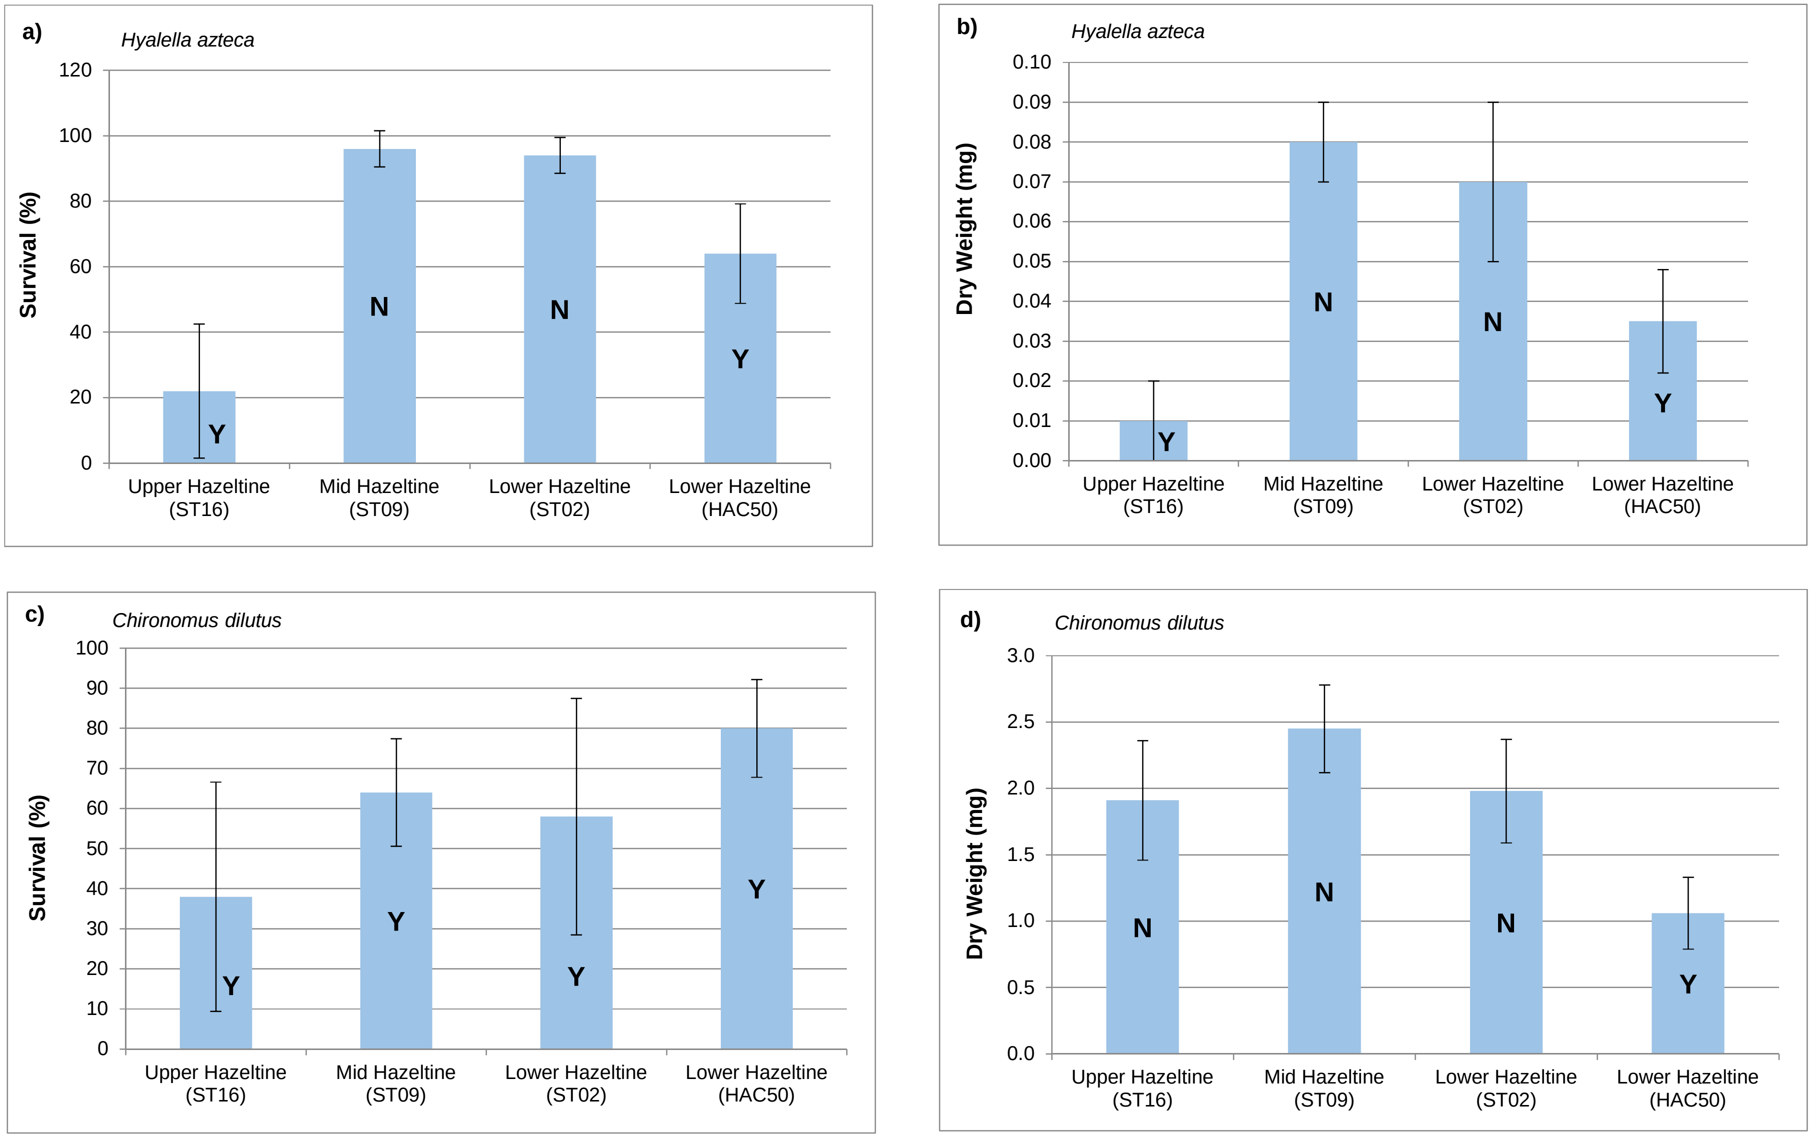

Figure 5.7: Toxicity tests of Hazeltine Creek sediment, Mount Polley Mine, 2014. Results for *Hyalella azteca* a) Survival (%), b) Dry Weight (mg) and *Chironomus dilutus* c) Survival (%), d) Dry Weight (mg). Error bars represent standard deviation. Letters represent significant differences (Y) or no differences (N) between samples and the control ($p < 0.05$). Control results are not shown.

Table 5.10: Spearman's Rank Correlation results for correlation of toxicity test results versus sediment physical characteristics, parameters of interest, indicator parameters, PCA axes and copper extracts (all in < 2mm sediment fraction) Hazeltine Creek sampling areas, Mount Polley Mine, 2014 [1].

Significant correlation; p-value < 0.0006 (Bonferroni corrected p-value for 80 comparisons).
Correlation scatterplot inspected; p <0.01.

[1] Values < method detection limit (MDL) were used at the MDL for calculations. Absolute survival and growth values were used for correations since all samples were run in the same laboratory batch using the same controls.

Note: n=15 for all correlations.

and characterize benthic invertebrate community condition relative to pre-event conditions (e.g., Minnow 2009).

5.5 Data Integration and Summary

Sediment collected from Hazeltine Creek following the dam failure is characterized by low TOC compared to pre-failure levels and concentrations of copper and iron greater than SQG PELs and pre-event concentrations. Concentrations of arsenic and nickel were greater than SQG TELs at a subset of sample locations and only in <63 µm sediment (not <2.0 mm sediment). Copper was more substantially elevated than any other analyte, with mean concentrations up to five times the PEL and 15 times background. Sediment geochemical evaluations indicated that, for most POIs and IPs, concentrations were mostly in the residual phase, a fraction that is not considered mobile or biologically available. However, copper was a notable exception, with the majority occurring in the "organic" phase (although this appears to be mineral), and with concentrations in the exchangeable, carbonate and easily reducible phases approaching pre-event concentrations. Separate integrated consideration of mineralogy, sequential extraction results and mineral solubility indicates that these forms would not be mobile under environmentally realistic conditions (SRK 2015).

Sediment toxicity testing indicated some adverse effects to both test species (*H. azteca* and *C. dilutus*), but also indicated no effect at some combinations of endpoint and location (e.g., no reduction in *H. azteca* survival and growth at the mid-stream area and no reduction in *C. dilutus* growth at three of four areas). Survival and growth of *C. dilutus* were weakly associated with concentrations of several POIs and IPs. Survival of *H. azteca* was positively correlated with percent fines and calcium, and growth of *H. azteca* was weakly associated percent fines and percent TOC in the positive direction, and with POIs and IPs (including exchangeable and organic copper) win the negative direction. These relationships suggest negative biological effects due to low TOC and elevated concentrations of failure-related metals including copper in selective extracts.

Overall, an impact of the dam failure was evident in sediment quality throughout Hazeltine Creek. Copper represents the analyte of greatest concern, both with respect to its absolute concentration relative to guidelines and its geochemical partitioning. Sediment toxicity testing confirmed effects on test organisms that were weakly associated with low TOC and elevated concentrations of POIs and IPs, including exchangeable and organic copper, but also indicated some instances of no toxicity.

6.0 POLLEY LAKE

Sediment quality impact characterization in Polley Lake included sediment chemistry, sediment geochemical characterization, sediment stratigraphy, toxicity testing, and benthic invertebrate community characterization (Table 4.1; Figure 4.3). Samples were collected from two areas at mid-depth (north and south sides of Polley Lake at approximately 20 m depth) and in two deep basins (also on the north and south sides of Polley Lake, at approximately 29 m depth). The deep basins were included because they have been sampled on several previous occasions, providing pre-event data for interpretation of impact. Bootjack Lake served as a reference for Polley Lake (Figure 4.3). Data Quality Assessment (DQA; Appendix C with supporting data in Appendix J) indicated that sediment quality data, toxicity test results and benthic invertebrate community data were of good quality and can therefore be used in the sediment quality impact characterization.

6.1 Sediment Physical and Chemical Characterization

Surficial sediment (top 5 cm) of Polley Lake was observed to be heterogeneous, typically composed of dark brown fines (consistent with pre-event and reference sediment) with varying quantities of grey fines either on top of the sediment or mixed into the sediment. In general, the sediment collected from the south side of Polley Lake was quite variable, with some samples being composed entirely of brown fines and others composed entirely of grey fines. This was especially true within the basin area POL-P2 and the two mid-depth areas closest to the southern end of the lake (POL-2-02 and POL-2-03), where the proportion of grey fines was roughly equal to or greater than the proportion of native brown fines collected. Sediment from the north side of Polley Lake showed a layering of grey fines over native brown to dark brown fines. Although the proportion of these layers varied among sampling stations, the native brown fines generally comprised the greater proportion of the sample, and in some instances the proportion of grey fines was fairly small.

Surficial sediments at the mid-depth areas and the basins of Polley Lake and Bootjack Lake (reference) were predominantly silt, with smaller fractions of sand and clay (Table 6.1; Appendix Tables E.15-E.16 and E.19-E.20). Mean total organic carbon (TOC) content of Polley Lake mid-depth sediment (approximately 0.8% at the south side and 3% at the north side; Table 6.1) was lower than that of mid-depth sediment from Bootjack Lake (approximately 18%; Table 6.1) and Polley Lake pre-event levels (mean 8.4%; Table 3.5). Mean TOC content was slightly lower in the Polley Lake basins (11.2% and 9.8%;

Table 6.1: Summary of sediment quality data for mid-depth and deep stations in Polley Lake and associated reference areas in Bootjack Lake, Mount Polley Mine, 2014. Metals data are based on the < 2mm fraction of sediment[1].

Value is > TEL. Values shown in bold text also exceeded highest detectable Reference Value (historical Polley Lake or 2014 Bootjack Lake 95th Percentile value) for either mid-depth or deep areas.

Value is > PEL. Values shown in bold text also exceeded highest detectable Reference Value (historical Polley Lake or 2014 Bootjack Lake 95th Percentile value) for either mid-depth or deep areas.

[1] Reported TOC, TN, pH and moisture data are based on bulk sediment. Data < method detection limit (MDL) were used at the MDL for calculation of summary statistics. Means are reported as < MDL if all the data used in their calculation were < MDL.

[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b); TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.

[3] The 5th percentile is reported for pH.

[4] Historic sediment metal concentrations are based predominantly on bulk sediment samples.

[5] Samples were collected using a sediment corer.

[6] Samples were collected using a petite ponar.

Table 6.1) relative to the Bootjack Lake basins (14.4% and 16.9%; Table 6.1) and Polley Lake pre-event levels (mean 18.2%; Table 3.5).

Copper and iron were the only analytes with concentrations in Polley Lake mid-depth sediment greater than guidelines (the TEL in the case of iron and the PEL in the case of copper) and reference concentrations (Tables 6.1 and 6.2; Figure 6.1). In the Polley Lake deep areas (POL-P1 and POL-P2), arsenic and copper were the only analytes with concentrations greater than guidelines (the TEL in the case of arsenic and the PEL in the case of copper) and reference concentrations in all basins, with zinc elevated at one area (POL-P1, the north basin) in <63 µm sediment only (Tables 6.1 and 6.2; Figure 6.1). Concentrations of five additional analytes were present in Polley Lake mid-depth and/or deep sediment (<2 mm) at concentrations more than two times greater than reference concentrations (calcium, molybdenum, sodium, strontium and titanium; Table 6.3). This list of IPs differs from that identified for Hazeltine Creek (due to the different applicable reference data), with the absence of silver and vanadium and the inclusion of strontium and titanium. One additional IP, tin, was identified on the basis of concentrations more than two times greater than reference concentration in <63 µm sediment of the Polley Lake basins (both P1 and P2; Table 6.3). Thus, in accordance with the framework set out in Section 4.0, arsenic, copper, iron, and zinc are designated as POIs and calcium, molybdenum, sodium, strontium, tin and titanium are designated as IPs.

Principal Components Analysis (PCA) of the mid-depth sediment data was effective in distinguishing sediments of Polley Lake from those of Bootjack Lake (reference) primarily on the basis of axis 1 scores, indicating coarser sediment (more sand and less clay), lower TOC content, and higher concentrations of a number of metals (arsenic, cobalt, copper, sodium, strontium, titanium and vanadium; Figure 6.2). PCA of deep basin sediment data was also effective in distinguishing sediments of Polley Lake from those of Bootjack Lake (reference) primarily on the basis of axis 1 scores, indicating more clay in Polley Lake sediments and more TOC in Bootjack Lake sediments and higher concentrations of a number of metals (arsenic, calcium, cobalt, copper, lithium, magnesium, potassium, sodium, strontium, titanium and vanadium) in Polley Lake sediments (Figure 6.3). PCA axis 2 served primarily to distinguish stations P1-01 and P1-02 on the basis of higher zinc concentrations (Figure 6.3). Overall, PCA assisted in confirming the importance of the POIs and IPs in describing spatial variability in sediment quality.

Of the five POIs and six IPs, sodium was the most substantially elevated in Polley Lake, with concentrations in the <2 mm sediment up to approximately six times reference and

Table 6.2: Summary of sediment quality data for mid-depth and deep stations in Polley Lake and associated reference areas in Bootjack Lake, Mount Polley Mine, 2014. Data are based on the < 63 µm fraction of sediment [1].

(blue) Value is > TEL. Values shown in bold text also exceeded highest detectable Reference Value (historical Polley Lake and 2014 Bootjack Lake 95th Percentile values) for either mid-depth or deep areas.

(orange) Value is > PEL. Values shown in bold text also exceeded highest detectable Reference Value (historical Polley Lake and 2014 Bootjack Lake 95th Percentile values) for either mid-depth or deep areas.

[1] Data < method detection limit (MDL) were used at the MDL for calculation of summary statistics. Means are reported as < MDL if all the data used in their calculation were < MDL.

[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b); TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.

[3] The 5th percentile is reported for pH.

[4] Historic sediment metal concentrations are based predominantly on bulk sediment samples.

[5] Samples were collected using a sediment corer.

[6] Samples were collected using a petite ponar.

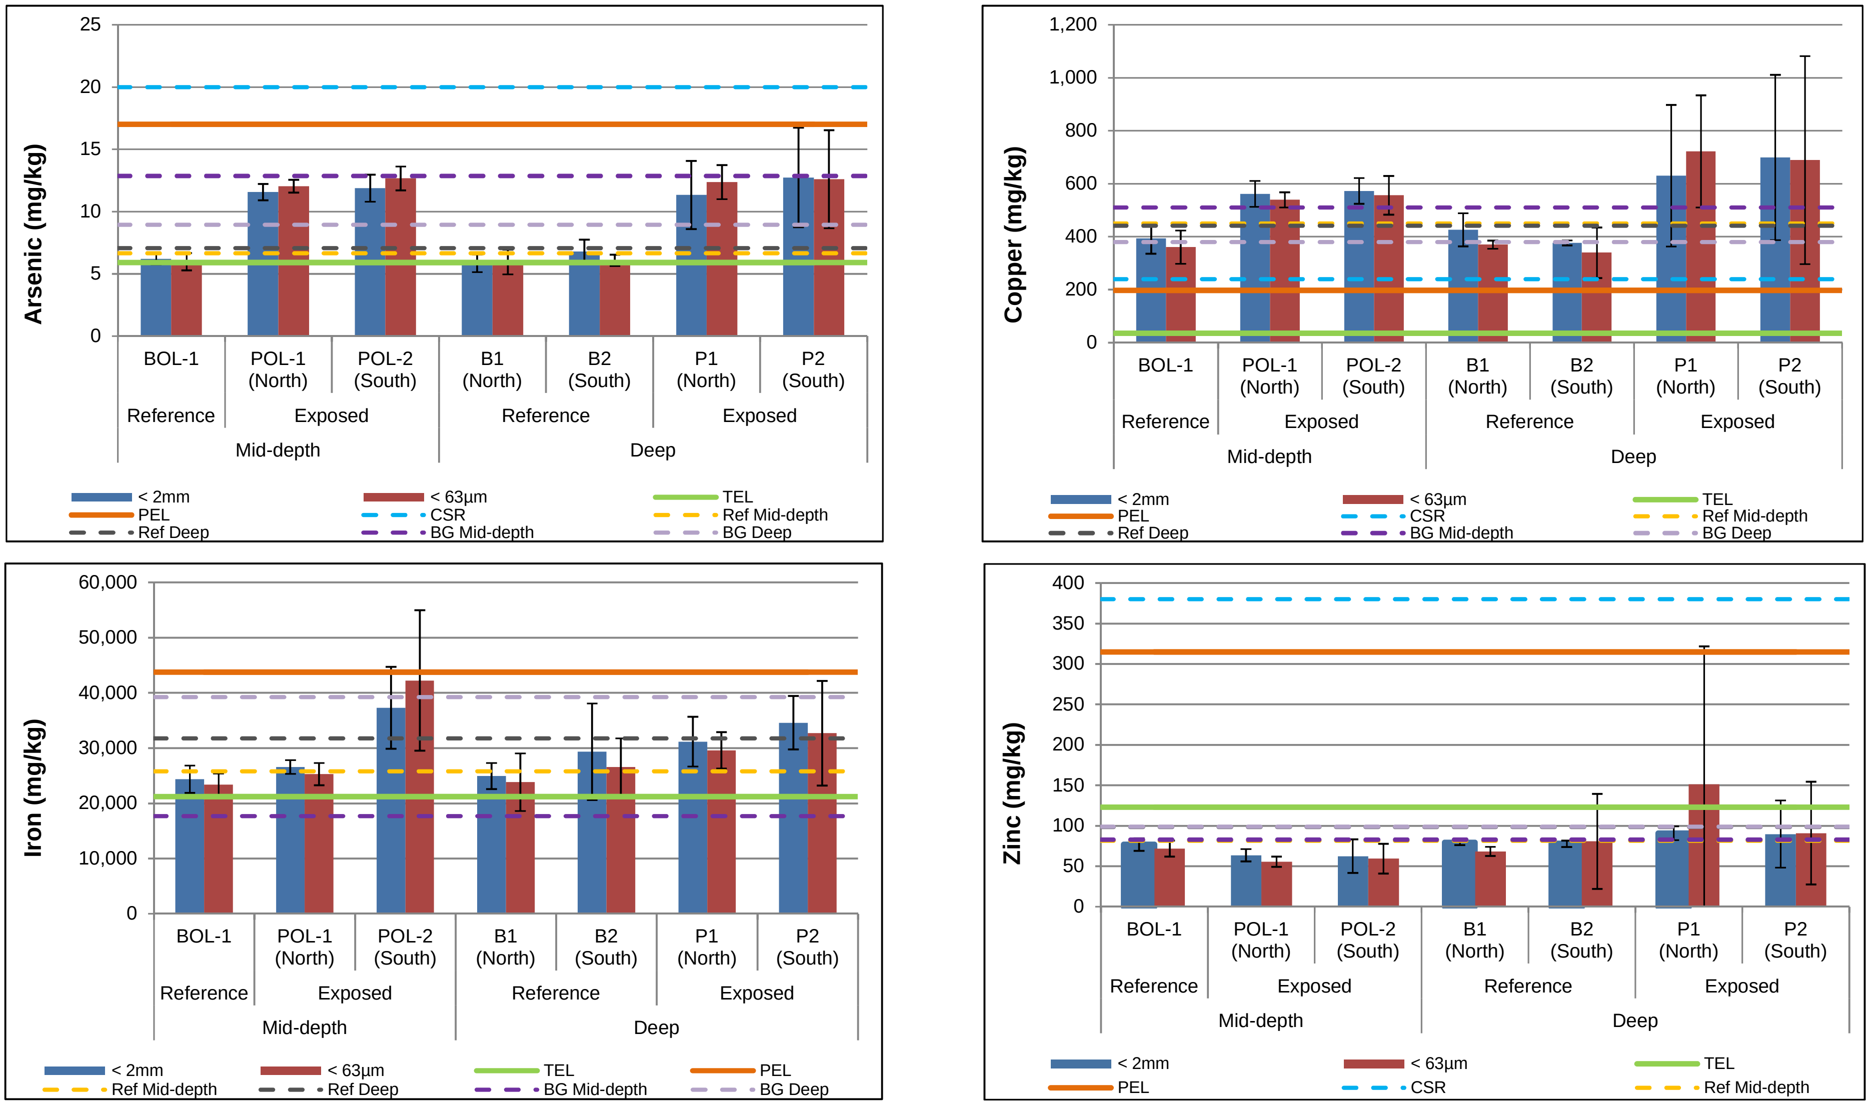

Figure 6.1: Mean metal concentrations (± t*SE) for parameters of interest in sediment from mid-depth and deep sampling areas of Polley Lake and associated reference lake (Bootjack Lake), Mount Polley Mine, 2014.

TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level; CSR = Contaminated Sites Regulation - Typical; BG = Historic 95th percentile for either mid-depth or deep areas. Ref Mid-depth and Ref Deep values were selected as the highest detectable Bootjack Lake 95th percentile value from the < 2mm and < 63 µm fractions within each sampling area (Mid-depth or Deep). Historic sediment metal concentrations are based predominantly on bulk sediment samples.

Table 6.3: Ratio of exposed mean to reference mean metal concentrations[1,2] in sediment from mid-depth and deep lake sampling areas of Polley Lake, Mount Polley Mine, 2014. Ratios with a value > 2 are highlighted.

[1] The highest mean concentration for each analyte from among Polley Lake historical data (1989 - 2012) and 2014 Bootjack Lake data for the associated sampling depth (mid-depth or deep) and sediment fraction (<63 µm or <2 mm) was used as the reference mean for calculation of the ratio.

[2] Mean values < method detection limit (MDL) were used at the MDL for calculation of exposed/reference ratios.

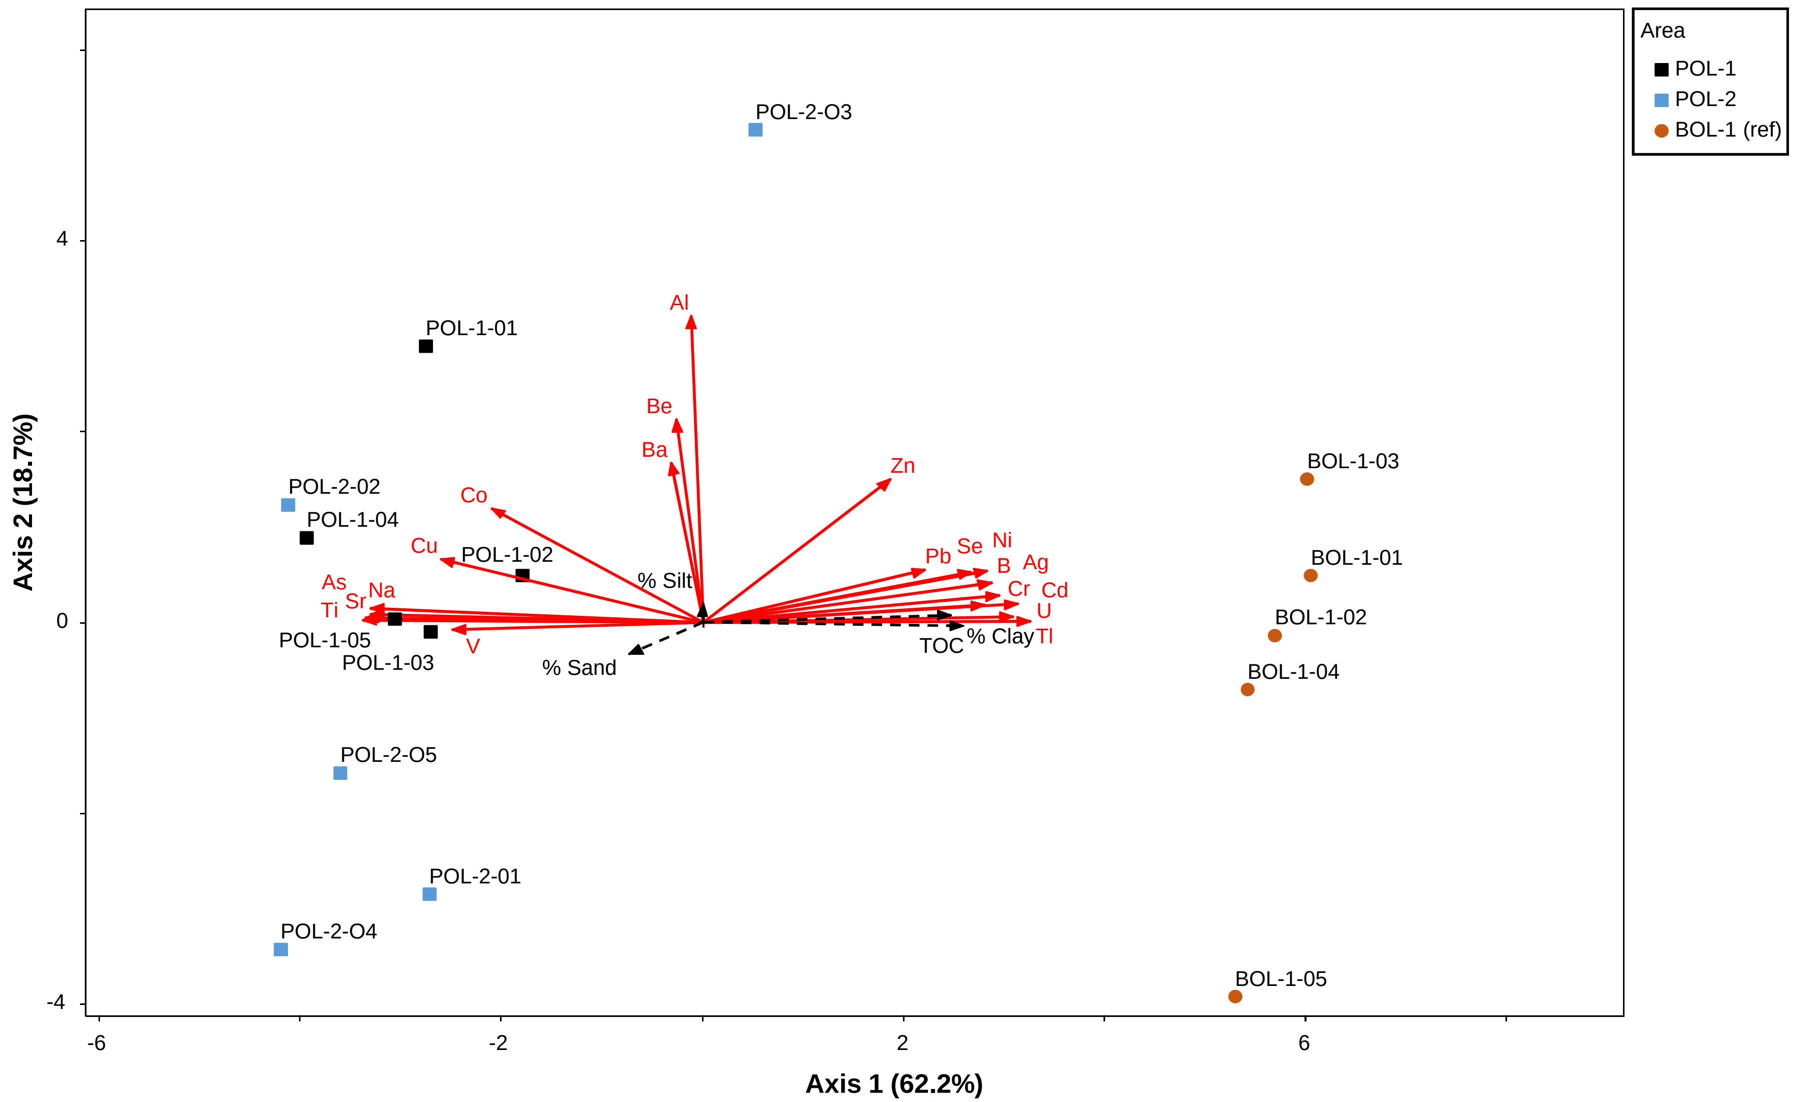

Figure 6.2: Biplot of principal component analysis (PCA) of metal concentrations in sediment (< 2mm fraction) from Polley and Bootjack Lake mid-depth sampling stations, Mount Polley Mine, 2014. Vector length is proportional to the magnitude of direct correlation of metals (solid red vector lines) and indirect correlation of sediment physical characteristics (black dashed vector lines) with PCA values of each axis (Appendix Tables E.23-E.24). Only metals with significant (p-value <0.010) Spearman's correlation and r-values > 0.7 with either axis are displayed, all sediment physical characteristics are displayed [a].

[a] Bismuth, and mercury were excluded from calculations due to a lack of variability in the data (all values for each analyte were the same), or an incomplete data set

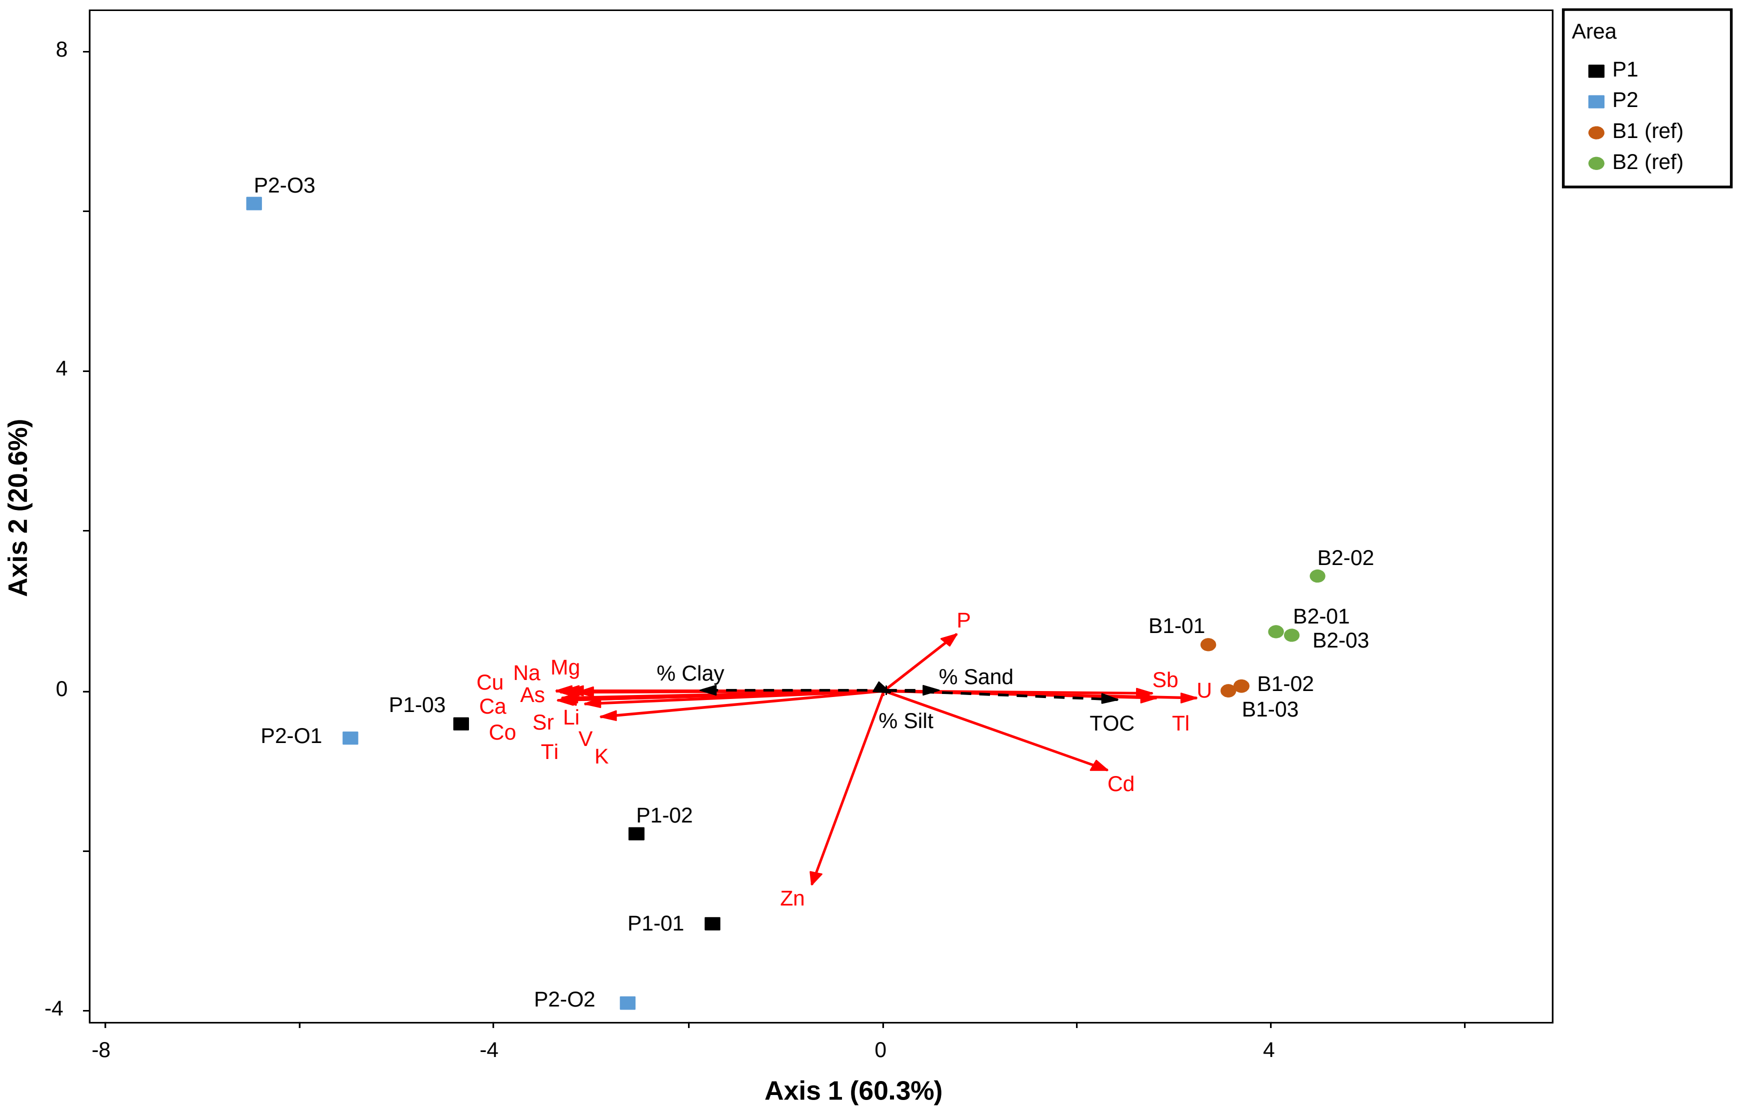

Figure 6.3: Biplot of principal component analysis (PCA) of metal concentrations in sediment (< 2mm fraction) from Polley and Bootjack Lake deep sampling stations, Mount Polley Mine, 2014. Vector length is proportional to the magnitude of direct correlation of metals (solid red vector lines) and indirect correlation of sediment physical characteristics (black dashed vector lines) with PCA values of each axis (Appendix Tables E.25-E.26). Only metals with significant (p-value <0.010) Spearman's correlation and r-values > 0.7 with either axis are displayed, all sediment physical characteristics are displayed [a].

[a] Boron, bismuth, and mercury were excluded from calculations due to a lack of variability in the data (all values for each analyte were the same), or an incomplete data set.

concentrations in the <63 µm sediment up to approximately five times reference (Table 6.3; Figure 6.4). Arsenic in all Polley Lake sediment was elevated to concentrations greater than reference and also to concentrations greater than the SQG TELs (but below SQG PELs). However, concentrations of arsenic at the mid-depth areas, but not in the basins, were lower than their pre-event concentrations (Figure 6.1). Copper concentrations were also elevated in all Polley Lake sediments to concentrations greater than reference and also to concentrations slightly greater than the SQG PELs. As with arsenic, concentrations of copper at mid-depth areas were similar to pre-event concentrations, whereas copper concentrations in the deep basins in 2014 were higher than at any other area, and also higher than pre-event concentrations (Figure 6.1). Concentrations of iron were notably elevated at one mid-depth area (POL-2; south side) to concentrations greater than reference, pre-event and approaching the SQG PEL (Figure 6.1). This elevation in iron concentration relative to other locations, particularly relative to the north side of Polley Lake (POL-1), was not observed for other POIs and IPs (Figures 6.1 and 6.4). Generally, there were few differences in POI and IP concentrations in sediment of the south and north sides of Polley Lake (Figures 6.1 and 6.4), suggesting a spatially consistent influence of the failure on sediment quality of Polley Lake.

Zinc was the only analyte with concentration correlated with percent fines (percent silt and clay), with a positive relationship largely driven by lower percent fines and zinc concentration at the Polley Lake mid-depth area 2 (south side; Table 6.4; Appendix Figure E.12). Concentrations of most POIs and IPs (arsenic, copper, iron, calcium, sodium, strontium and titanium) were negatively correlated with total organic carbon content, with lowest concentrations occurring with highest TOC in reference Bootjack Lake (Table 6.4; Appendix Figures E.13-E.14). One the one hand, this is consistent with a dam failure-influence defined by the input of inorganic sediments with elevated POI and IP concentrations to Polley Lake. On the other hand, concentrations of zinc were positively correlated with TOC, with highest concentrations of zinc occurring at the Polley Lake deep basins (Appendix Figure E.12).

6.2 Sediment Geochemical Characterization

As previously indicated, there are numerous factors that affect the bioavailability of sediment-associated metals. While metal concentrations that are below the sediment quality guidelines generally provide a reliable indicator of an absence of effect, sediment quality results that exceed those benchmarks provide a less reliable indication that effects are probable. Geochemical characterization can assist in characterizing the potential mobility and bioavailability of metals associated with mine-influenced sediments.

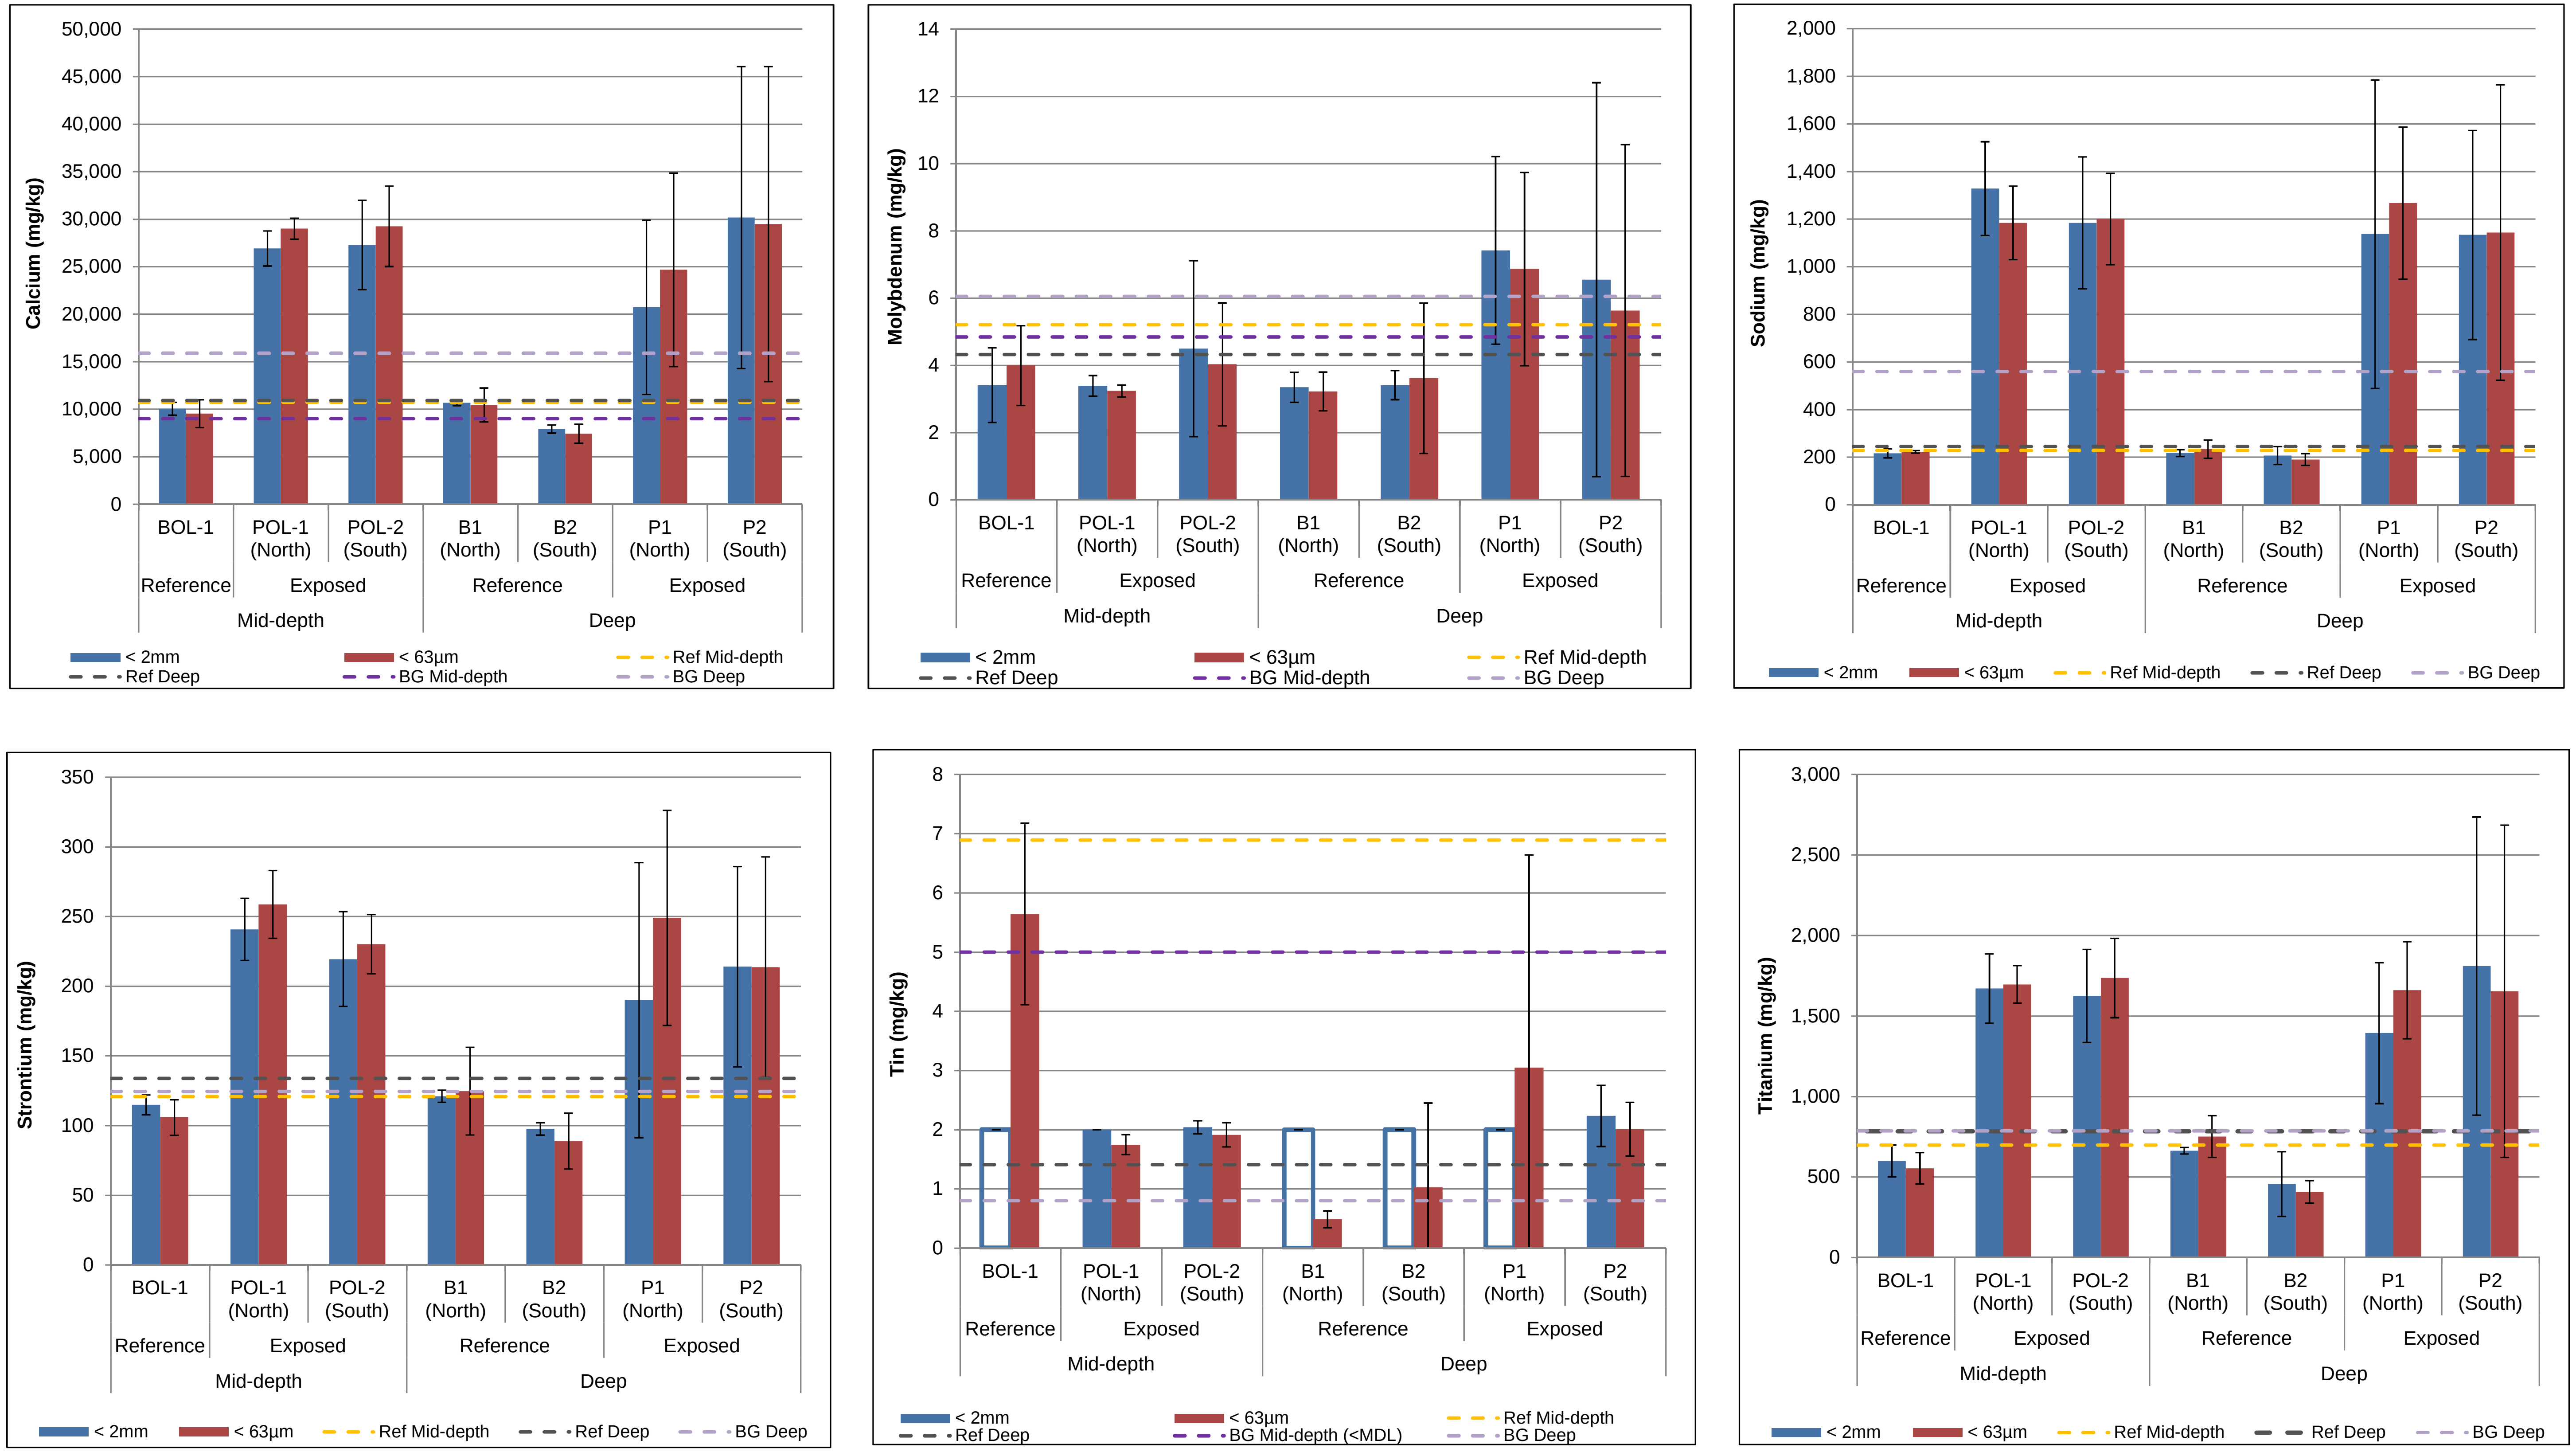

Figure 6.4: Mean metal concentrations (± t*SE) for indicator parameters in sediment from mid-depth and deep sampling areas of Polley Lake and associated reference lake (Bootjack Lake), Mount Polley, 2014. Hollow bars indicate all values used to calculate the mean were < the method detection limit (MDL).

BG = Historic 95th percentile for either mid-depth or deep areas, and are based predominantly on bulk sediment samples.
Ref Mid-depth and Ref Deep values were selected as the highest detectable Bootjack Lake 95th percentile value from the < 2mm and < 63 µm fractions within each sampling area (Mid-depth or Deep).

Table 6.4: Spearman's Rank Correlation results for concentrations of parameters of interest and indicator parameters (in < 2mm sediment fraction) relative to % fines (silt and clay) and total organic carbon in sediment from Polley and Bootjack Lake mid-depth and deep lake sampling areas, Mount Polley Mine, 2014 [1].

Correlation scatterplot inspected; p < 0.01

[1] Values < method detection limit (MDL) were used at the MDL for calculations.

Note: n = 27 for all correlations.

As observed with Hazeltine Creek sediments, selective extractions indicated that concentrations of most POIs and IPs were primarily in the residual phase; that is, they could only be extracted by the strongest acid digest (a combination of concentrated nitric and hydrochloric acid; Table 6.5; Figure 6.5; Appendix Tables E.35-E.38; Appendix Figures E.15-E.16). As previously discussed, residual metals are unlikely to be mobilized under any conditions that could realistically occur in the environment, nor in interactions with aquatic organisms (i.e., contact with the gill or ingestion) and are therefore considered not biologically available (e.g., Tessier et al. 1979; Campbell and Tessier 1996). Exceptions included copper and molybdenum, which had greatest concentrations of in the "organic" phase (Figure 6.5; Table 6.5; Appendix Tables E.35-E.38). As previously discussed (Section 5.2), it is likely that the "organic" phase represents mineral copper. Concentrations of copper in selective extraction fractions 1 to 3 (exchangeable + carbonate bound + reducible) were greater than reference (Figure 6.5). However, separate integrated consideration of mineralogy, sequential extraction results and mineral solubility indicates that these forms would not be mobile under environmentally realistic conditions (SRK 2015). Therefore, sediment copper also appears to be present in Polley Lake sediments in forms that are not mobile and this immobility suggests limited concern for aquatic biota.

Shake flask tests indicated low mobility of metals associated with Polley Lake sediments, with copper and manganese being the only metals mobilized in shake flask tests (at mid-depth areas only) to concentrations greater than British Columbia Water Quality Guidelines (BCWQG) and reference (Table 6.6; Appendix Tables E.39-E.42). The identification of copper and manganese as more mobile than other metals is consistent with the results of the selective extractions above. In the case of copper, the highest mean concentration mobilized in the shake flask tests (0.032 mg/L at the south side of Polley Lake; Area POL-P2) was the same as reference (BOL-B2; Table 6.6). As previously stated, BCWQG do not apply to sediment leachates, but are used herein as an indication of low mobility.

Acid-Base accounting results indicated lower potential for acid generation in sediments collected from Polley Lake than in reference sediments collected from Bootjack Lake (Appendix Tables E.12 and E.43-E.44). Mean neutralization potential ratio (NPR; the ratio of neutralization potential to maximum potential acidity) was highest at the mid-depth area at the south side of Polley Lake (NPR 9.9 at POL-2, where NPR greater than 4 indicates no potential for Acid Rock Drainage; Price 1997). Decreasing NPR with distance from the point of impact on Polley Lake (south side) indicates that acid potential associated with

Table 6.5: Summary of selectively extracted (Tessier extraction) metals data for Polley Lake mid-depth and deep sampling areas and associated Bootjack Lake reference areas, Mount Polley Mine, 2014. Data are based on <2 mm fraction of sediment [1,2]. Only metals with detectable concentrations are displayed.

(blue) Value is > TEL. Values shown in bold text also exceed associated Bootjack Lake Mid-depth or Deep Reference 95th Percentile values.
(orange) Value is > PEL. Values shown in bold text also exceed associated Bootjack Lake Mid-depth or Deep Reference 95th Percentile values.

[1] Data < method detection limit (< MDL) were used at the MDL for the calculation of summary statistics. Means are reported as < the highest displayed MDL if all the data used in their calculation were < MDL.
[2] Samples were collected using a sediment corer or petite ponar.
[3] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b); TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.
[4] Contaminated Sites Regulation (Government of British Columbia 1996)

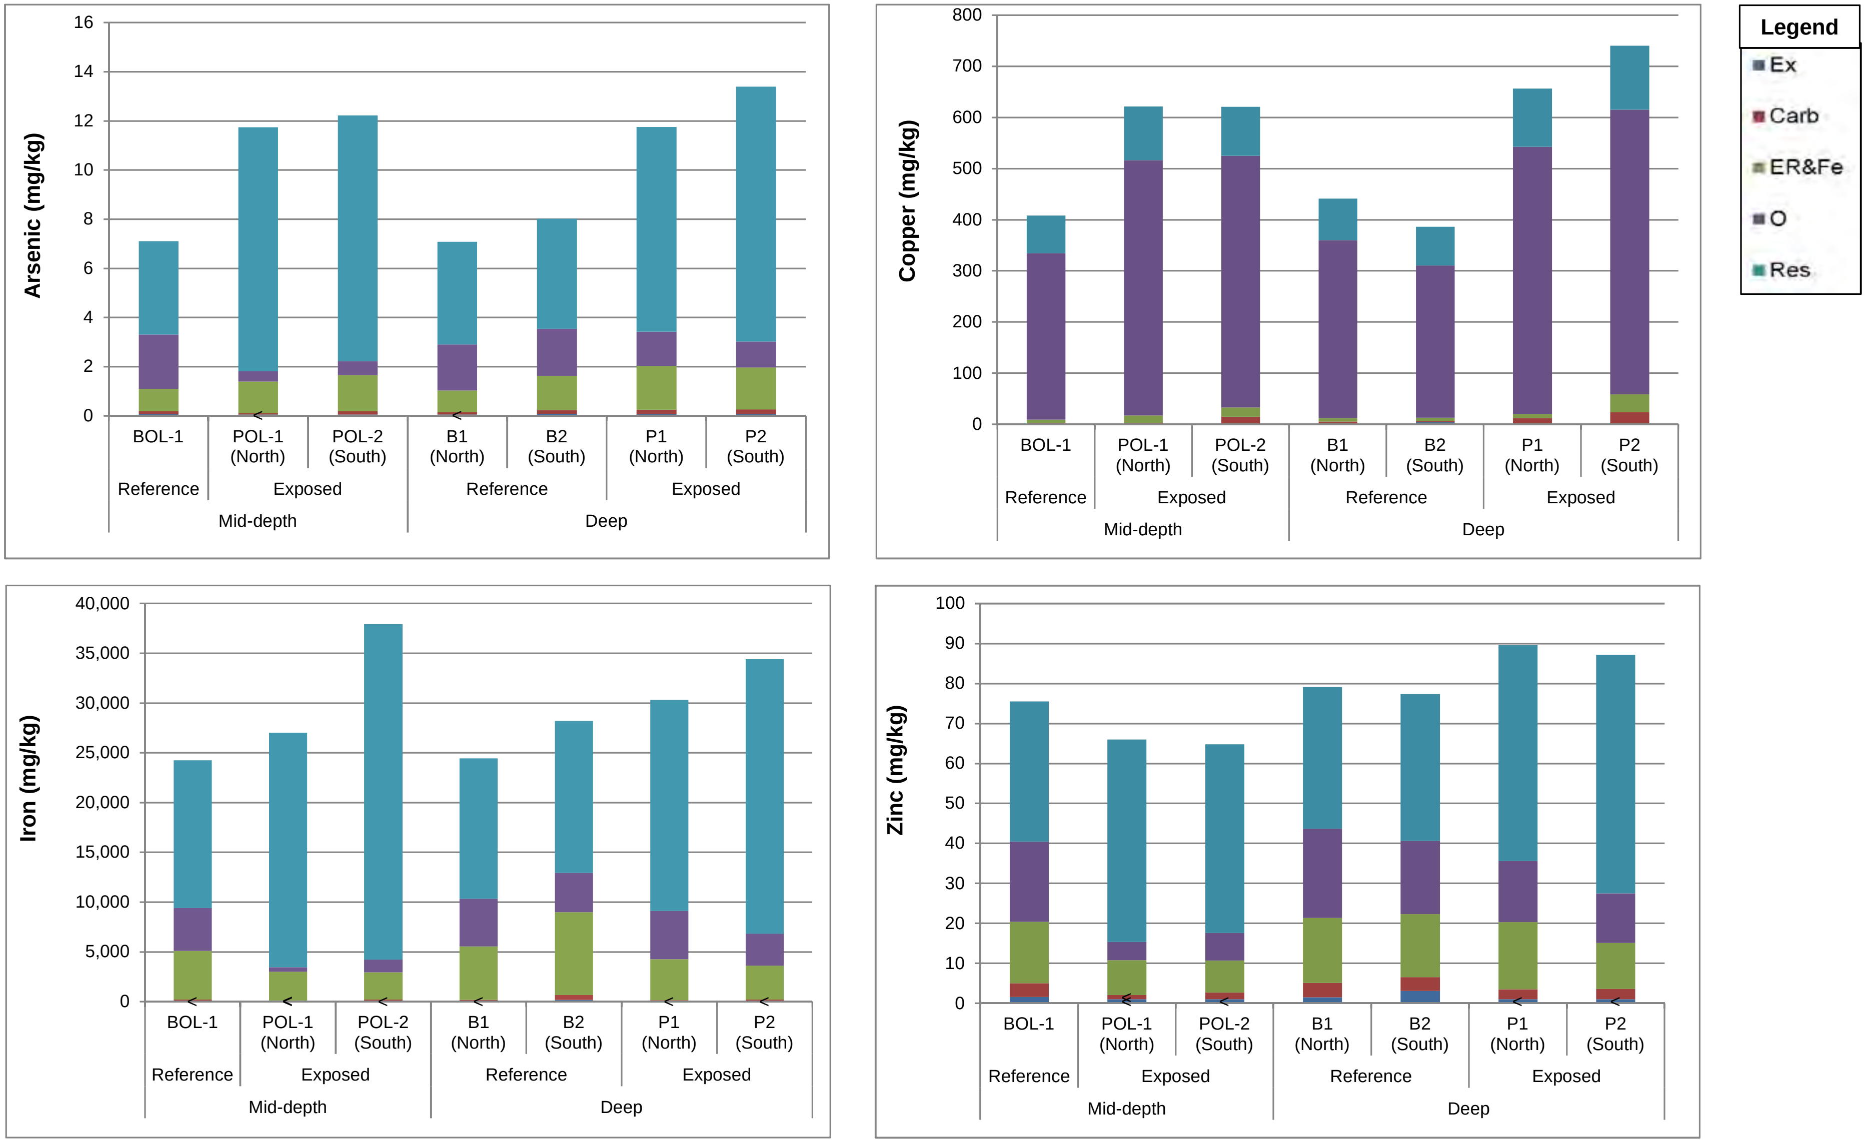

Figure 6.5: Mean concentrations of selectively extracted parameters of interest in sediment from mid-depth and deep sampling areas of Polley Lake, Mount Polley, 2014. Selective extractions included Exchangeable & Adsorbed Metals (Ex), Carbonate Metals (Carb), Easily Reducible Metals and Iron Oxides (ER&Fe), Organic Bound Metals (O), and Residual Metals (Res).

Mean values < MDL are indicated with a < symbol. Means are reported as < MDL if all data used in their calculation were < MDL.

Table 6.6: Summary of leachable (Shakeflask) metals data for sediment from Polley Lake mid-depth and deep sampling areas and associated Bootjack Lake reference areas, Mount Polley Mine, 2014. Data are based on bulk sediment [1,2]. Only metals with detectable concentrations are displayed.

[2] Samples were collected using a sediment corer or petite ponar.

[3] British Columbia Water Quality Guidelines (BCMOE 2015a, 2015b); W=Working guideline; A=Approved guideline. See Appendix Table E.10 for derivation of hardness-based guidelines.

[4] Hazardous Waste Regulation (Government of British Columbia 1988)

the impacted sediments was lower than reference and far-field sediments (i.e., the mine-influenced materials had higher neutralization potential than native sediment).

6.3 Sediment Stratigraphy

Sediment cores for characterization of vertical stratigraphy (examination of physical and chemical changes with depth below surface) were collected from two locations in Polley Lake - the basins P1 and P2 (Figure 4.3). Two cores were collected from each location; one for sediment chemistry profiling and one for pore-water chemistry profiling.

6.3.1 Sediment Core Observations

North Basin (P1)

A comparison of the two sediment cores from the North Basin, collected at the same time and location, documented the spatially heterogeneous nature of the observable deposition of mine-derived material in Polley Lake; cores collected side-by-side differed in appearance (Appendix Figure E.17). The core collected for sediment chemistry analysis showed little observable intrusion of grey-coloured material whereas the core collected for pore-water chemical analysis showed intrusion of grey-coloured material throughout the generally brown sediment. Although smearing of sediment and tailings material would confound any conclusions derived from external core observations, it was evident that the two cores differed. Therefore, pore-water and sediment chemistry profiles cannot be considered synchronous. The heterogeneous deposition of tailings in Polley Lake was also noted in the general sediment quality characterization (Section 6.1). In the top 1 cm of the sediment chemistry core, a very fine layer of grey material was deposited over black sediment and the amount of grey material present in each section decreased with depth. By 3 cm in depth, the core was over 95% black in colour, and the black sediment dominated to the bottom of the 23 cm long core. Observations made during the sectioning of the core collected for pore-water chemical analysis indicated that some grey material was noted in the top 0 to 7 cm, but in general the sediment was brown, getting gradually darker down-core. The sediment material became clay-like in consistency at around 16 cm depth.

South Basin (P2)

A comparison of the two sediment cores from the south basin (Appendix Figure E.18), further confirmed the heterogeneous nature of the sediment and observable deposition of mine-derived material in Polley Lake. As a result, the cores collected for sediment chemistry and pore water could not be considered synchronous. The core collected for sediment chemistry analysis showed intrusion of grey-coloured material in the majority of the length of the core. In contrast, the core collected for pore-water chemical analysis showed little intrusion of grey-coloured material throughout the generally brown sediment. Sectioning of the cores showed that the majority of grey material was located in the 6 to 10 cm sections. The top 1 cm of the core had a thin layer of fine grey material deposited over brown sediment; but by 2 cm depth the sediment was mostly brown in colour. Grey sediment started to become observable by 5 cm with approximately 50% tailings in the 6 to 10 cm sections. The amount of grey material present in each section decreased to nil by 13 cm. Observations indicated that the material was not mixed with natural sediment and indicated the depth at which tailings intruded into natural sediment (i.e., to 13 cm; Appendix Figure E.19). This apparent intrusion of grey material into native sediment (as opposed to settling on top of native sediment) may help to explain why sediment in Polley Lake was so different among cores collected from the same location at the same time.

Observations made during the sectioning of the core collected for pore-water chemical analysis indicated that some grey material was present in the top 3 cm. The remainder of the core was brown in colour and grey material was not observed. Additionally, sediment was likely reducing as a sulphurous odour was detected when the glove bag (used to keep the sediment core samples in an inert atmosphere) was periodically opened.

6.3.2 Sediment Chemistry Profiles

North Basin (P1)

The chemistry of the top 12 cm of sediment (in 1 cm sections) collected at P1 was screened against BC SQGs and against sediment quality data collected from the same station prior to the tailings dam failure. Concentrations of copper and manganese were both greater than PEL throughout the whole core (Figure 6.6). However, concentrations of manganese did not exceed the pre-dam failure sediment concentration collected from the same station in 2012 (1,630 mg/kg; Table 3.5). For copper, only the top 0 to 2 cm of sediment exceeded the pre-dam failure concentration of 369 mg/kg (Table 3.5). Other elements (arsenic, iron, and nickel) were above the TEL, but below the PEL. The top 2 cm of sediment iron and arsenic concentrations in 2012 prior to the dam failure were 35,100 mg/kg, and 8.86 mg/kg respectively (Table 3.5), and current (2014) sediment core concentrations of iron, arsenic and nickel concentrations were similar.

In general, the sediment chemistry profiles of the core agreed with the observations from sectioning the core. Only copper showed elevated concentrations in the top sections (compared to lower sections) of the core, and was also elevated above the 2012 copper

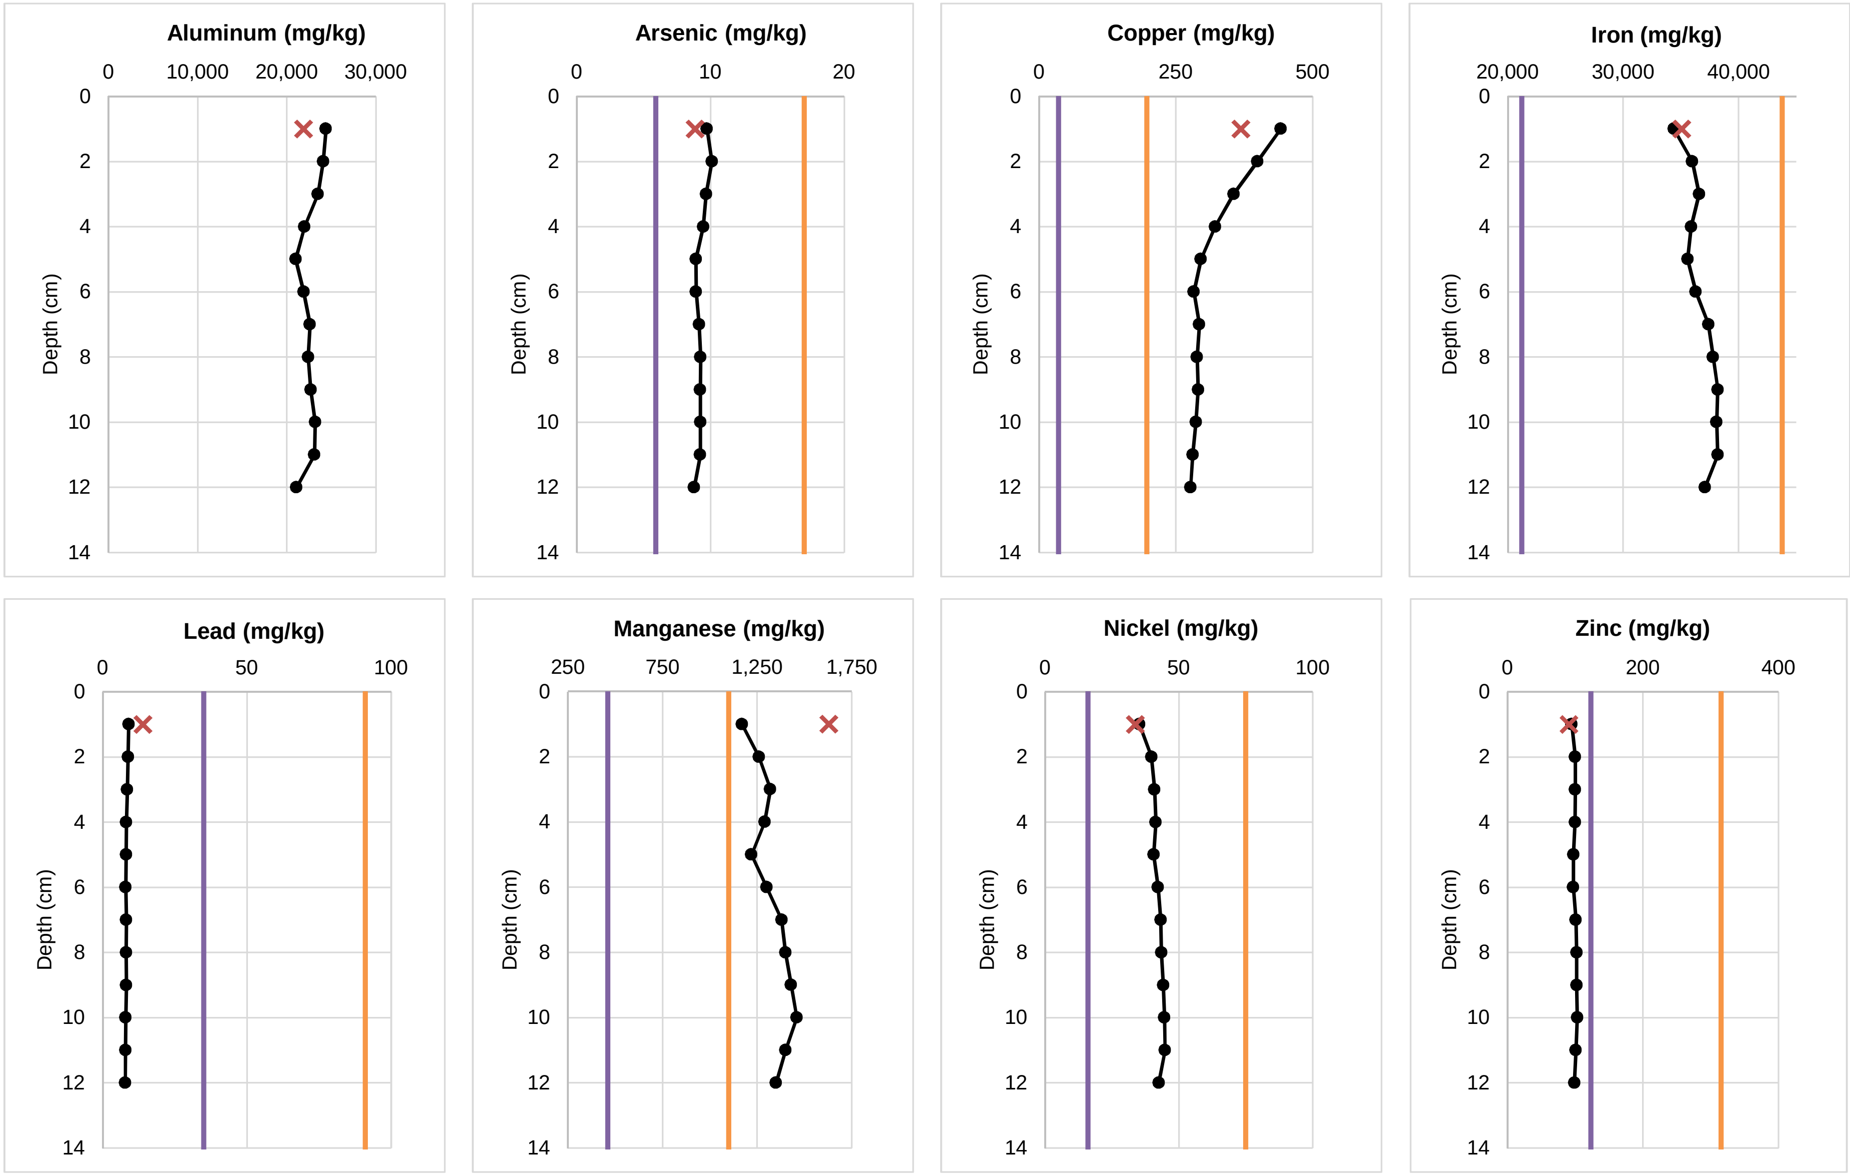

Figure 6.6: Sediment chemistry profiles of aluminum, arsenic, copper, iron, lead, manganese, nickel and zinc from the northern station (POL-P1-PW) of Polley Lake in September 2014 (black dots) and May 2012 (red X; Minnow 2014). Threshold Effect Level (TEL) is displayed in purple, while the Probable Effect Level (PEL) is in orange.

concentration in the 0 to 2 cm sections. The depth profile of copper may reflect a general accumulation of copper, associated with the ore body and/or mining activity over time, rather than an influence of the tailings dam failure.

Sediments were likely under reducing conditions given the low dissolved oxygen concentrations observed in the water column at depths greater than 7 m (Golder 2015). Any decrease in concentrations of arsenic, iron, manganese and nickel in the top section relative to the lower sections could be due to post-depositional reductive dissolution of iron and manganese, and elements associated with them (i.e., arsenic and nickel). This may be a dominant process compared to any elevated sediment concentrations associated with the thin layer of grey tailings material that was observed to have deposited over the sediment. Elevated sediment concentrations relative to the sediment quality guidelines (arsenic, copper, iron, manganese and nickel) in this specific core may be due to naturally elevated concentrations and/or some past influence of local geology or mine activity and subsequent sequestration in sediment. In general, this sediment chemistry profile is not reflective of any strong influence of recently deposited material.

South Basin (P2)

Copper concentration throughout the core collected at the Polley Lake south basin (P2) was greater than the PEL and was also greater than the 2012 concentration of 253 mg/kg collected from the same location (Figure 6.7; Table 3.5). Arsenic, iron, nickel, and manganese concentrations were all elevated above the TEL; however all were also at or below the 2012 sediment concentration collected from the same location (Table 3.5), although arsenic at a depth of 6 to 10 cm was elevated to a concentration greater than in 2012 (see below). The elevation of copper throughout the core to concentrations greater than in 2012, indicates an influence of the dam failure at this location.

Sediment core observations identified the greatest influence on sediment quality in sediment sections at a depth of 6 to 10 cm below surface. This was generally corroborated by the sediment concentration profiles of aluminum, arsenic, copper and iron (Figure 6.7), two of which are POIs (copper and iron; Section 6.1). Although manganese concentrations in 2014 were generally lower than in 2012, the manganese concentration profile also reflected a failure-related influence at 6 to 10 cm.

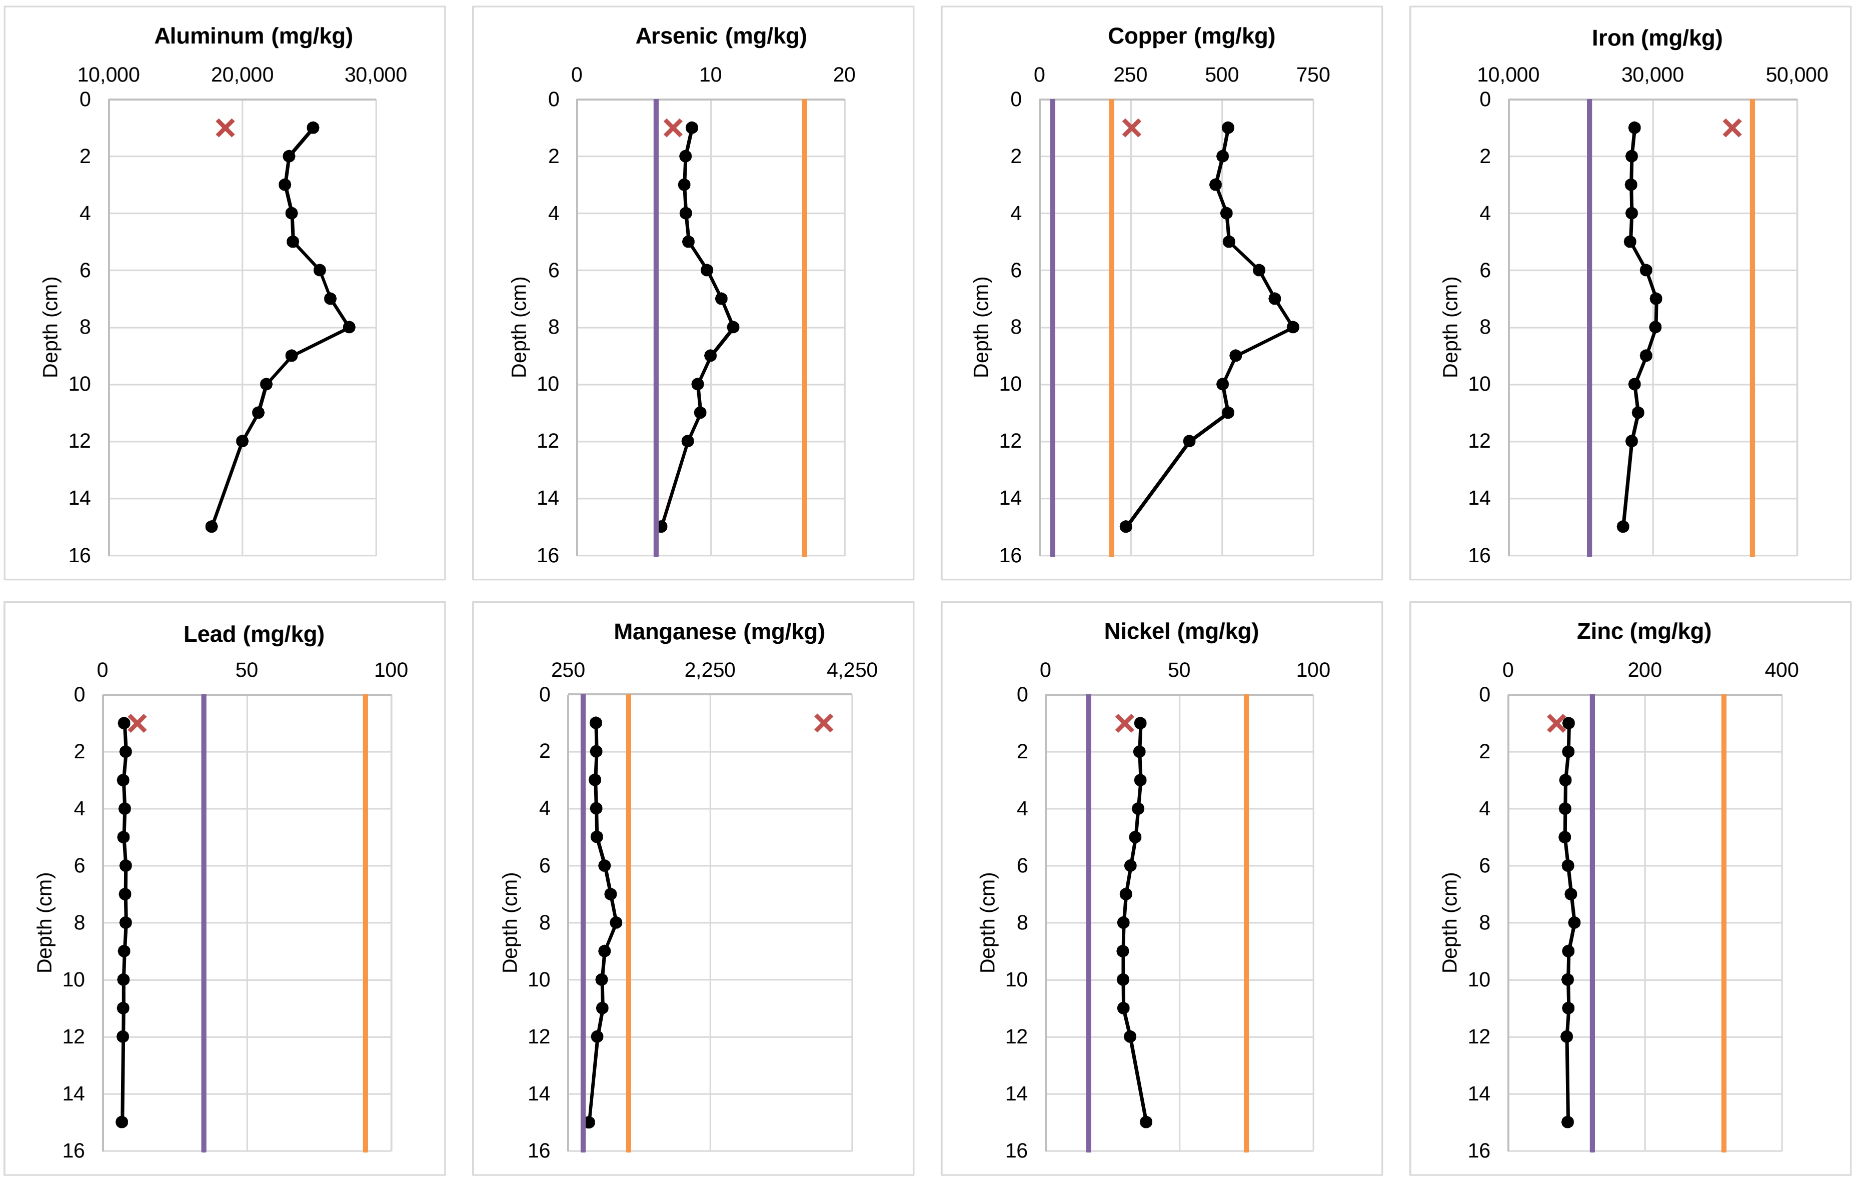

Figure 6.7: Sediment chemistry profiles of aluminum, arsenic, copper, iron, lead, manganese, nickel and zinc from the southern station (POL-P2-PW) of Polley Lake in September 2014 (black dots) and May 2012 (red X; Minnow 2014). Threshold Effect Level (TEL) is displayed in purple, while the Probable Effect Level (PEL) is in orange.

6.3.3 Sediment Pore-Water Profiles

North Basin (P1)

Observations made while sectioning the core from P1 for pore-water profiling indicated the presence of grey material mostly in the top 7 cm. Pore-water concentrations of arsenic, copper, lead and sulphate were elevated in the top 11 cm (Figure 6.8). Pore-water iron concentrations showed depletion around 2 to 10 cm, which was likely associated with changing redox conditions as the tailings material and natural sediments interacted. There is some evidence to indicate that the overlying water and natural sediments were under reducing conditions (Golder 2015) while the tailings materials were oxidized. This would result in increased soluble concentrations of iron at the interface of natural sediment and mine-derived material, and in close proximity to the sediment-water interface where reducing conditions occurred. Manganese (which undergoes reduction at a similar cell potential to iron) showed no such depletion in concentration, which may reflect the moderate concentration of manganese in the tailings.

The low concentrations of nitrite and sulphide in the top 11 cm suggest that conditions were oxidizing. The subsequent increase in both nitrite and nitrate concentration at 12 cm suggest that the naturally deposited sediment may be a greater source of nitrate compared to the tailings. The presence of increased nitrite at 12 cm suggests sub-oxic conditions. The depletion of nitrate deeper into the sediment core suggests that sediments become more reducing with depth. Limited extractable pore-water from sediment resulted in low sample volumes for sulphide analysis and subsequent poor detection limits for sulphide, compared to Polley Lake station P2 sediment pore-water samples.

It is likely that because Polley Lake is dimictic (mixes completely twice per year), although tailings were oxidized at the time of sampling, over time the deposited materials may become reducing as, during summer and winter, both the water column above, and the sediments below the deposited tailings will be reducing. Therefore, the reductive dissolution of iron-containing materials is possible and may result in the remobilization of other metals associated with it – the most likely candidate for this would be arsenic. However, the iron-containing tailings (i.e., magnetite sands; SRK 2015) may not have been deposited in Polley Lake to a large spatial extent (SRK 2015), and iron concentrations do not appear to have been elevated compared to those observed in 2012 (Table 3.5). Furthermore, separate evaluation of potential post-depositional mobility indicated very low risk of metal mobilization under reducing conditions (SRK 2015).

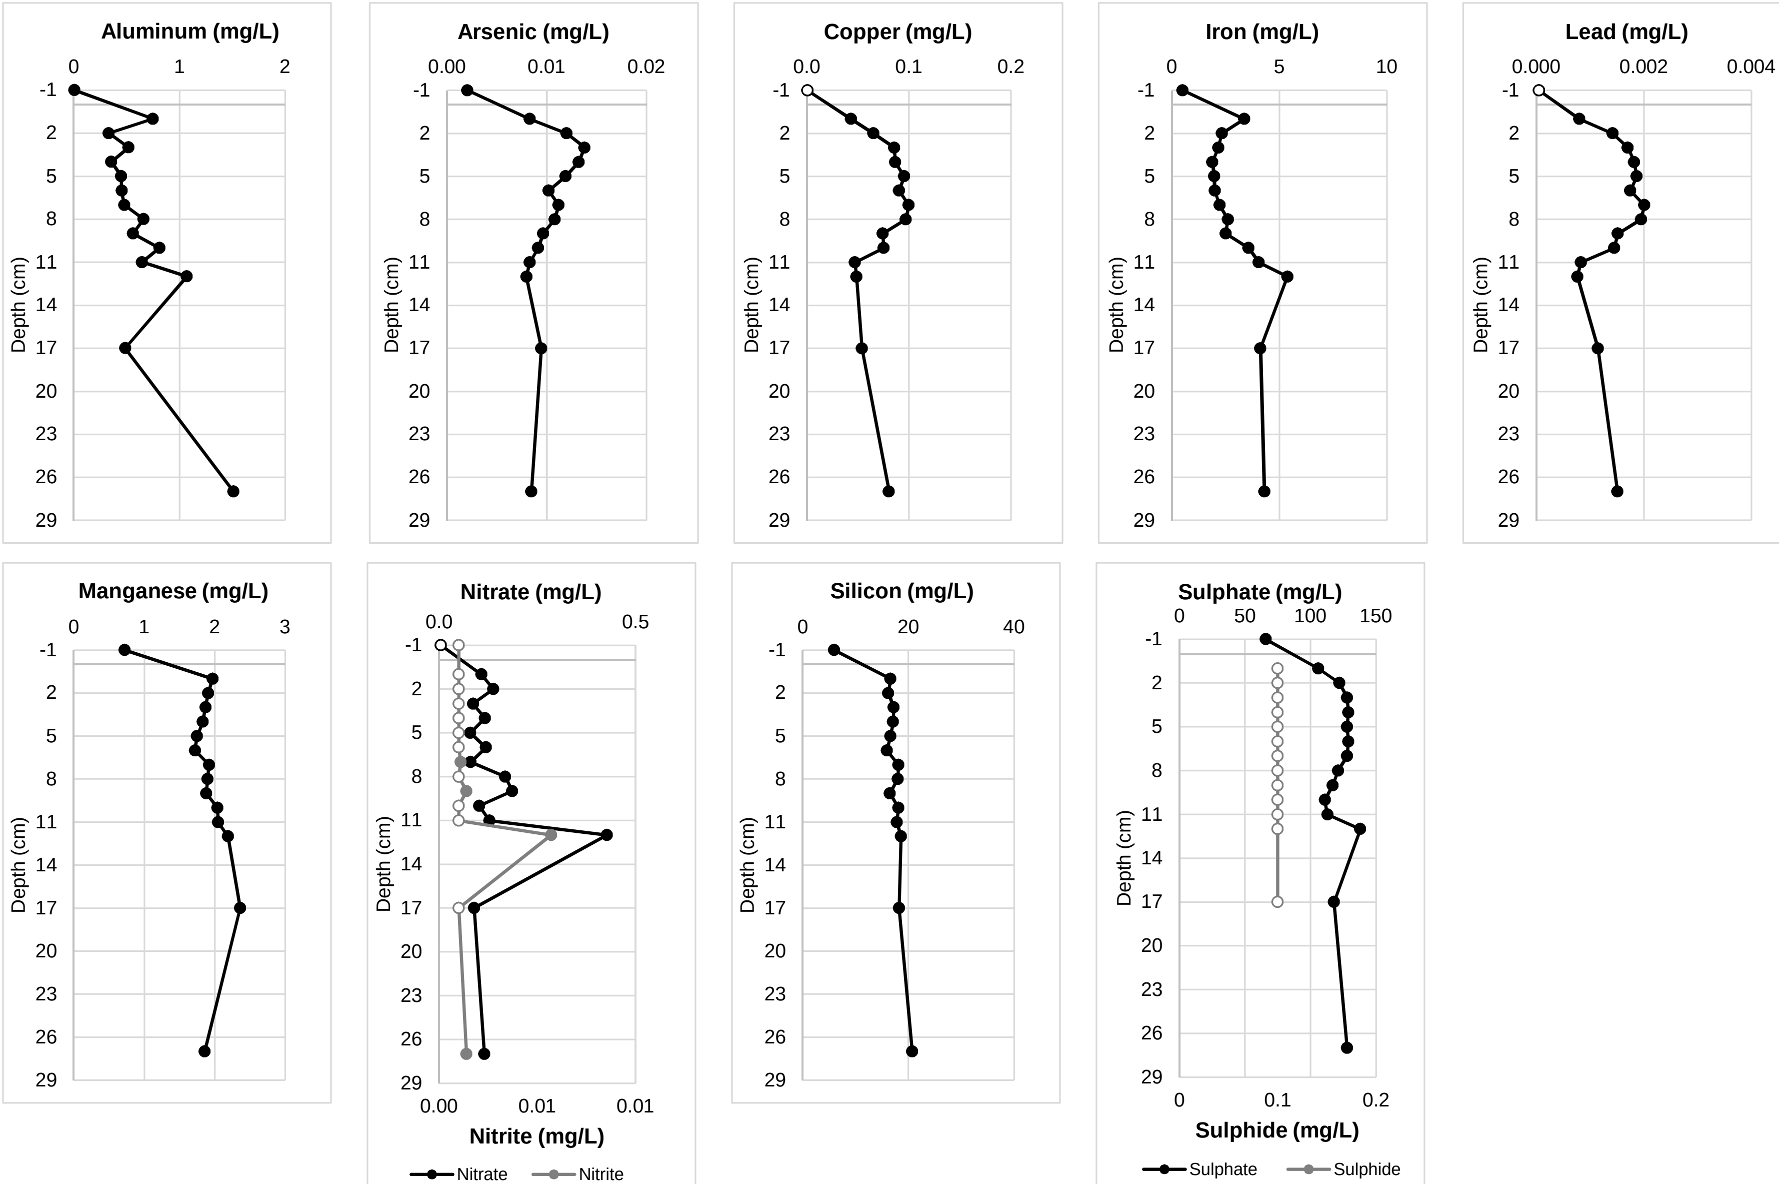

Figure 6.8: Pore water profiles of aluminum, arsenic, copper, iron, lead, manganese, nitrate, nitrite, silicon, sulphate, and sulphide from the northern station (POL-P1-PW) of Polley Lake, September 2014. Open data markers (o) indicate that the concentration was below the Method Detection Limit (MDL) [1].

[1] Analyte concentrations shown at a depth of -1 cm indicate concentrations in overlying water samples collected at POL-P1-PW.

South Basin (P2)

Core observations indicated that grey materials were present in the top 0 to 3 cm only. In general, pore-water profiles of the mine-associated elements (arsenic, copper, iron) showed no predominant pattern associated with the observed location of the mine-derived material (0 to 3 cm; Figure 6.9). The 0 to 1 cm sediment section pore-water concentrations were somewhat elevated in iron, arsenic, and copper, but in general, pore-water metal concentrations gradually increased with depth. Sulphide concentrations also increased with depth indicating that metals generally became more soluble as sediment conditions became more reducing. Sulphate and nitrate were not depleted, therefore sediment conditions were probably sub-oxic, not sulphidic. Thus, sediment conditions were likely sufficiently reducing for the reductive dissolution of oxidized iron (and the co-dissolution of metals associated with iron oxyhydroxides), but not sulphidic (i.e., no significant precipitation of iron sulphides would occur). This area would therefore have the same potential to reduce iron oxides and associated metals remobilizing them as described for Polley Lake station P1.

It is possible that the majority of iron associated with the source materials may be associated with the larger sand particles (i.e., magnetite sands; SRK 2015), rather than the grey fines. These larger particles may not have been deposited into Polley Lake to a large spatial extent compared to the grey tailings (SRK 2015). Therefore, the potential for the post-depositional reduction of iron and associated release of co-precipitated metals may be low in Polley Lake (as this is a sorptive process that occurs when the secondary mineral, amorphous iron oxyhydroxides precipitate from solution), and the form of iron in magnetite sands is not amorphous, but actually made up of primary minerals (i.e., predominantly magnetite). This is consistent with separate evaluation of potential post-depositional mobility, which indicated very low risk of metal mobilization under reducing conditions (SRK 2015).

6.4 Sediment Toxicity

Sediment toxicity testing indicated no instances of significantly reduced survival or growth of the freshwater/brackish water amphipod *Hyalella azteca* in Polley Lake sediments relative to concurrent laboratory controls and both references (Figure 6.10; Appendix Table F.1; Appendix Figures F.1-F.2). Absolute survival (i.e., non-normalized) ranged from 90% at POL-1 to 98% at POL-2 and at POL-P1; Appendix Tables F.3-F.4). Relative growth in Polley Lake sediments was greater than 100% in all but one area - POL-P1 (Polley Lake North basin), where it was 57% of reference (Appendix Tables F.3-F.4). At the Polley Lake basins (POL-P1 and POL-P2), there were no instances of significantly

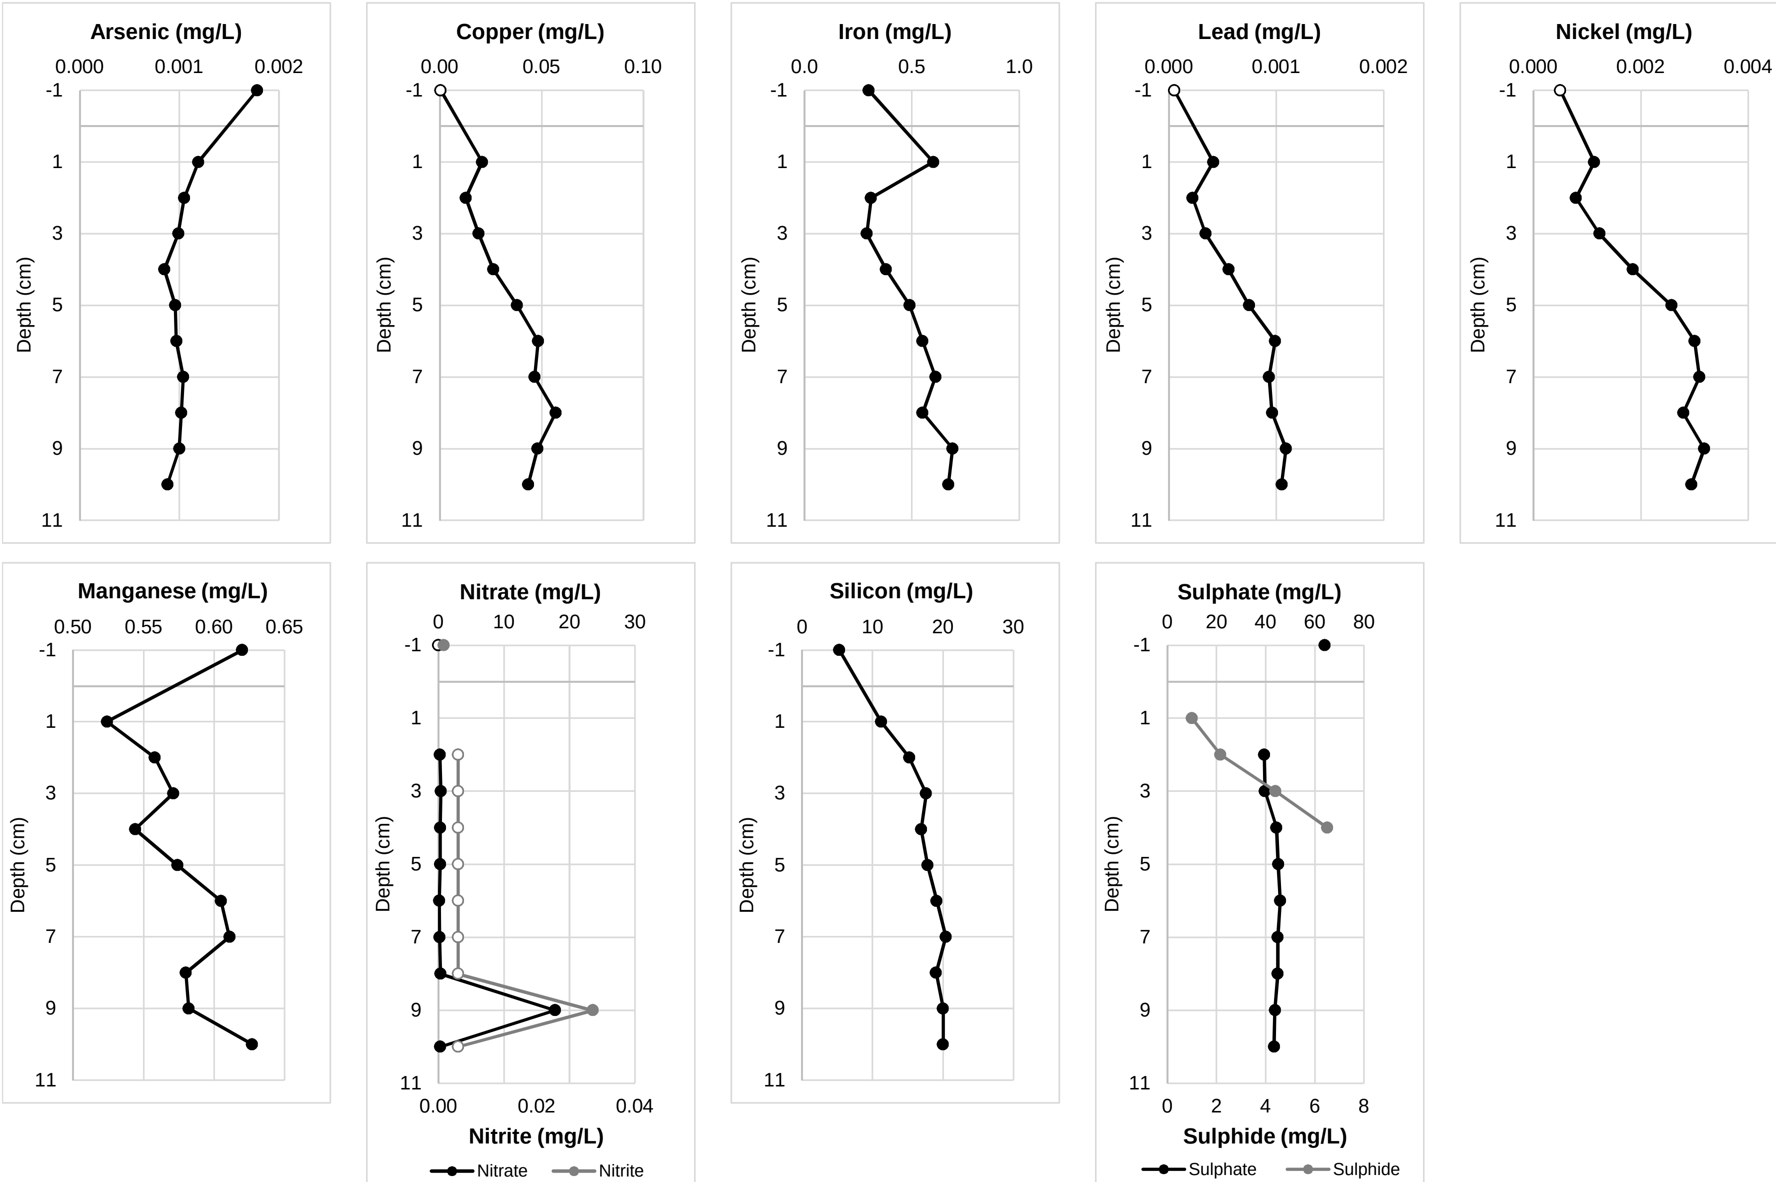

Figure 6.9: Pore water profiles of arsenic, copper, iron, lead, nickel, manganese, nitrate, nitrite, silicone, sulphate, and sulphide from southern station (POL-P2-PW) of Polley Lake, September 2014. Open data markers (o) indicate that the concentration was below the Method Detection Limit (MDL).

[1] Analyte concentrations shown at a depth of -1 cm indicate concentrations in overlying water samples collected at POL-P2-PW.

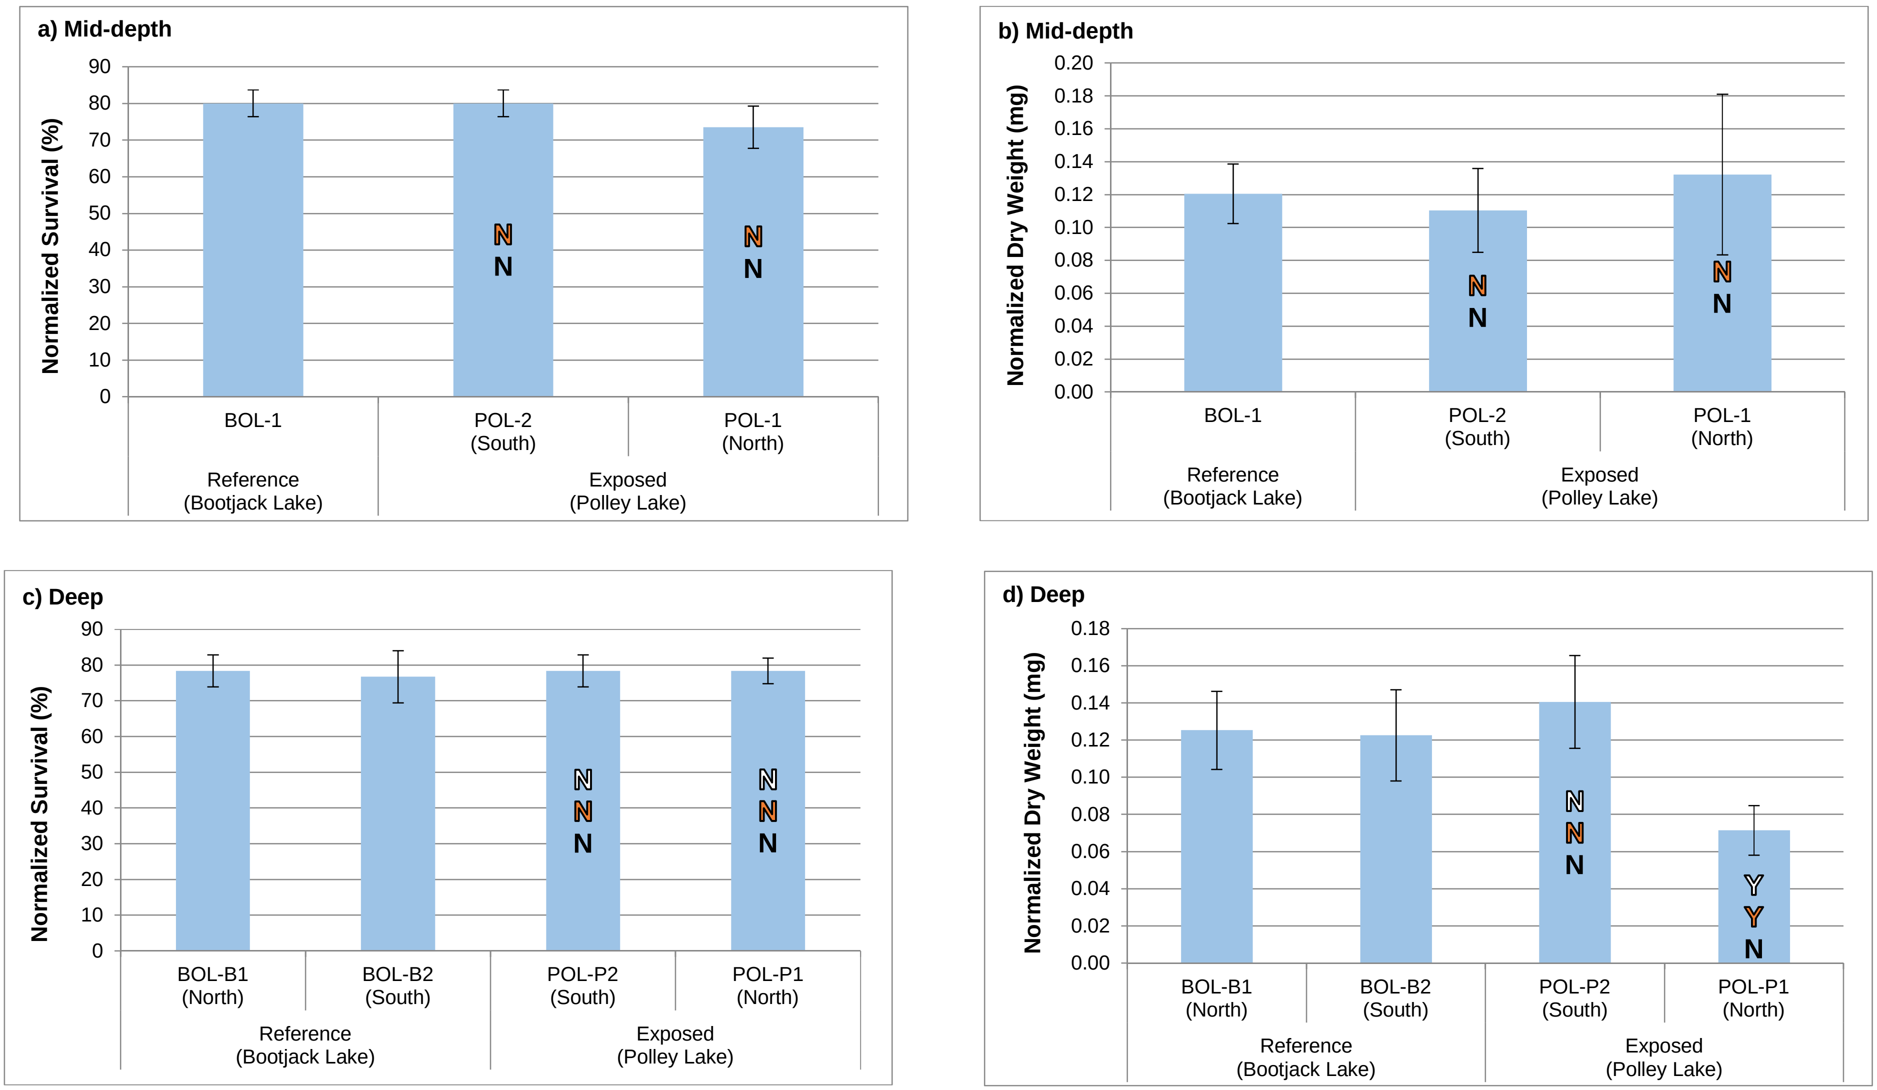

Figure 6.10: Toxicity tests of Polley and Bootjack Lake mid-depth and deep sediment on *Hyalella azteca* , Mount Polley Mine, 2014. Results for mid-depth a) Normalized Survival (%), b) Normalized Dry Weight (%), and deep c) Normalized Survival (%), d) Normalized Dry Weight (%). Error bars represent standard deviation. Control results are not displayed.

reduced survival or growth of the freshwater midge *Chironomus dilutus* relative to concurrent laboratory controls and both references (Figure 6.11; Appendix Table F.1). However, at area POL-2 (mid-depth at the south side of Polley Lake), survival, but not growth, was significantly reduced relative to concurrent laboratory controls and reference (Figure 6.11; Appendix Table F.1; Appendix Figures F.3-F.4). Absolute survival (i.e., non-normalized) of *C. dilutus* at area POL-2 was 64% (Appendix Tables F.5-F.6). No significant reductions in either survival or growth were observed at area POL-1 (mid-depth at the north side of Polley Lake; Figure 6.11; Appendix Table F.1). Overall, the toxicity data indicate very few effects in Polley Lake, the one exception being a modest reduction in survival of *C. dilutus* at area POL-2.

6.5 Benthic Invertebrate Community

Benthic invertebrate community samples of mid-depth areas of Polley Lake were compared to a reference area in Bootjack Lake (Table 4.1; Figure 4.2) in a Control-Impact (CI) design. In addition, samples from the Polley Lake deep areas (Basins P1 and P2) were compared to the Bootjack Lake reference using a before-after-control-impact (BACI) design based on data collected in 2014 and those collected at the same locations in 1999 (Beak 2000). Although the BACI design is considered to be an “optimal” study design (e.g., Green 1979), some caution must be applied in its interpretation due to the different benthic laboratories that provided the taxonomic analyses for the two studies (i.e., before and after). In addition, care must be taken in a BACI analysis to resist the temptation to interpret “area” effects when significant interactions “area*time” have been identified in the two-way ANOVA. Samples were collected by petite ponar grab sampler at five stations per area at the mid-depth areas and three stations per area at the basins.

6.5.1 Primary Metrics

Mean benthic organism density (individuals/m^2) and taxon richness were significantly lower at both Polley Lake mid-depth areas (POL-1 [north] and POL-2 [south]) relative to the Bootjack Lake reference (Figure 6.12; Appendix Table G.2). However, low density and low taxon richness were also observed in baseline studies conducted in 1995 and 1996 (Tables 3.6 and 3.8). Simpson’s diversity did not differ significantly among areas, but variability was high (Figure 6.12). Lastly, Simpson’s Evenness was significantly greater at both Polley Lake mid-depth areas than at the Bootjack Lake reference (Figure 6.12), presumably reflecting the presence of fewer taxa (communities represented by fewer taxa generally have greater evenness). Overall, the primary metrics indicate a potential impact to the mid-depth benthic invertebrate community of Polley Lake as evident in significantly lower density and taxon richness than reference. A low number of

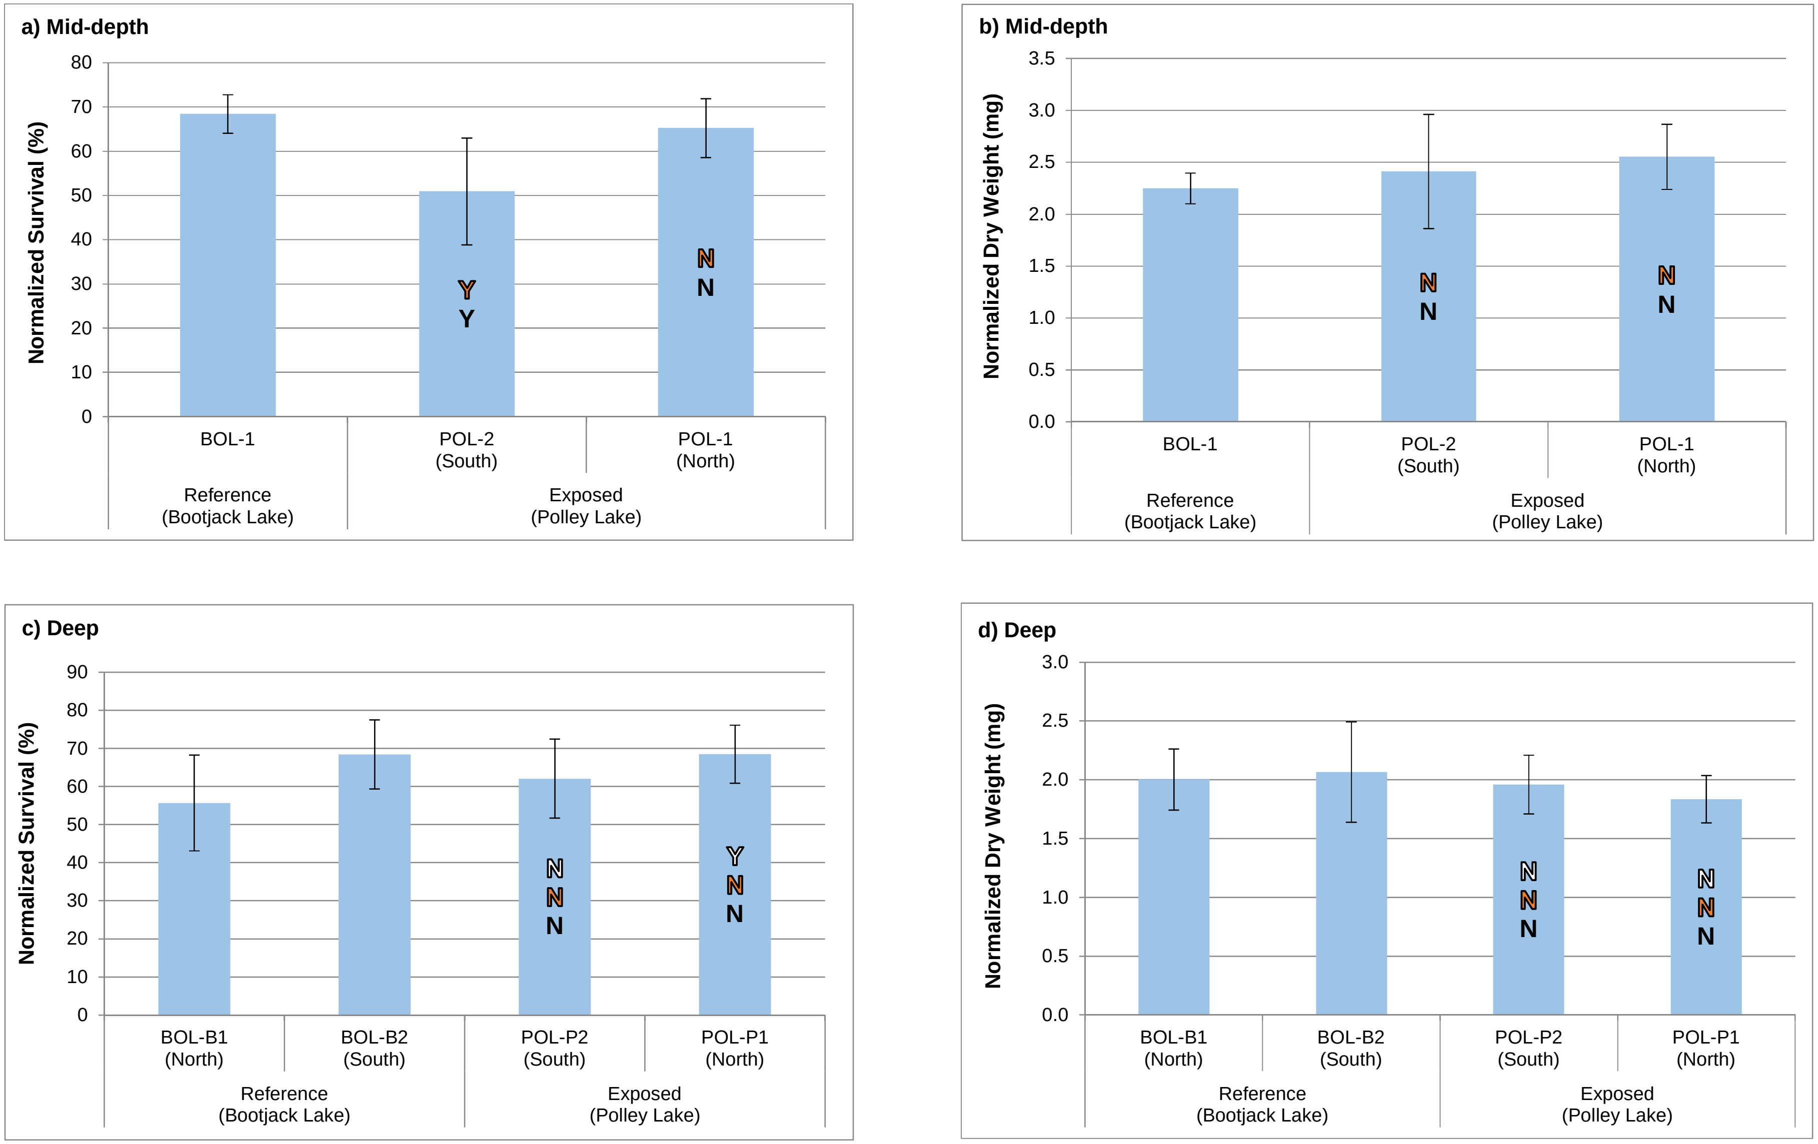

Figure 6.11: Toxicity tests of Polley and Bootjack Lake mid-depth and deep sediment on *Chironomus dilutus*, Mount Polley Mine, 2014. Results for mid-depth a) Normalized Survival (%), b) Normalized Weight (%), and deep c) Normalized Survival (%), d) Normalized Dry Weight (%). Error bars represent standard deviation. Letters represent significant differences (Y) or no differences (N) between samples and the Control (Black), Reference 1 (Orange) and Reference 2 (White) ($p < 0.05$). Control results are not displayed.

Different letters above data points indicate areas that were significantly different ($p < 0.1$).

taxa relative to reference can be indicative of a degraded benthic invertebrate community (Pielou 1974; Begon et. al. 1996).

Benthic sampling at deep area P2, the Polley Lake south basin, yielded no benthic invertebrates, indicating a direct impact of the dam failure. At area P1, located at the north side of Polley Lake (opposite the area of tailings input to Polley Lake), BACI indicated that Simpsons Evenness increased from 1999 more than it did at reference (which was similar in 1999 and 2014; Figure 6.13; Appendix Table G.8). Of the endpoints for which BACI differences (area*time) were not identified between P1 and reference (note that it is not defensible to evaluate endpoints in area comparisons when a significant area*time interaction has been identified), density and taxon richness were significantly lower at P1 than at the Bootjack reference (11.5 per m^2 vs. 2,140 per m^2, and 1.33 vs. 3.33; Figure 6.14; Appendix Tables G.9 and G.10), suggesting an impacted benthic invertebrate community. However, as noted above, low density and taxon richness were also observed in baseline studies conducted in 1995 and 1996 (Table 3.6).

6.5.2 Community Composition

Dominant invertebrate taxon groups at the Polley and Bootjack Lake mid-depth areas and basins included oligochaete worms, non-biting midges (Chironomidae), mites (Acari), and EPT taxa (Ephemeroptera, Plecoptera, Trichoptera – mayflies, stoneflies and caddisflies; Figure 6.15; Appendix Tables G.3-G.4).

The Bray-Curtis index of dissimilarity (BC index) indicated that the community composition of both Polley Lake mid-depth areas differed from that of the Bootjack Lake reference area (Figure 6.16; Appendix Table G.2). Community differences detected by the BC index are non-directional and not necessarily related to chemical exposure. That is, communities may be significantly dissimilar due to chemical effects or to natural factors (e.g., subtle habitat differences). No statistically significant differences in the proportions of key benthic invertebrate taxa were observed among exposed and reference areas (Figure 6.16). A difference in community composition was observed on CA axis 2 (which explained 22.6% of community variance; Appendix Table G.2), based on which POL-1 (the north side of Polley Lake) differed from reference (Bootjack Lake) and POL-2 (the south side of Polley Lake; Figure 6.16). Area POL-1 had high positive scores on CA axis 2, indicating high relative abundance of the non-biting midge (chironomid) *Procladius* and simultaneous low relative abundance of diurnally-planktonic *Chaoborus* larvae, whereas both BOL-1 and POL-2 had low CA axis 2 scores, indicating higher relative abundance of *Chaoborus* and variable abundance of *Procladius* (Figure 6.16; Appendix Table G.5; Appendix Figure G.1).

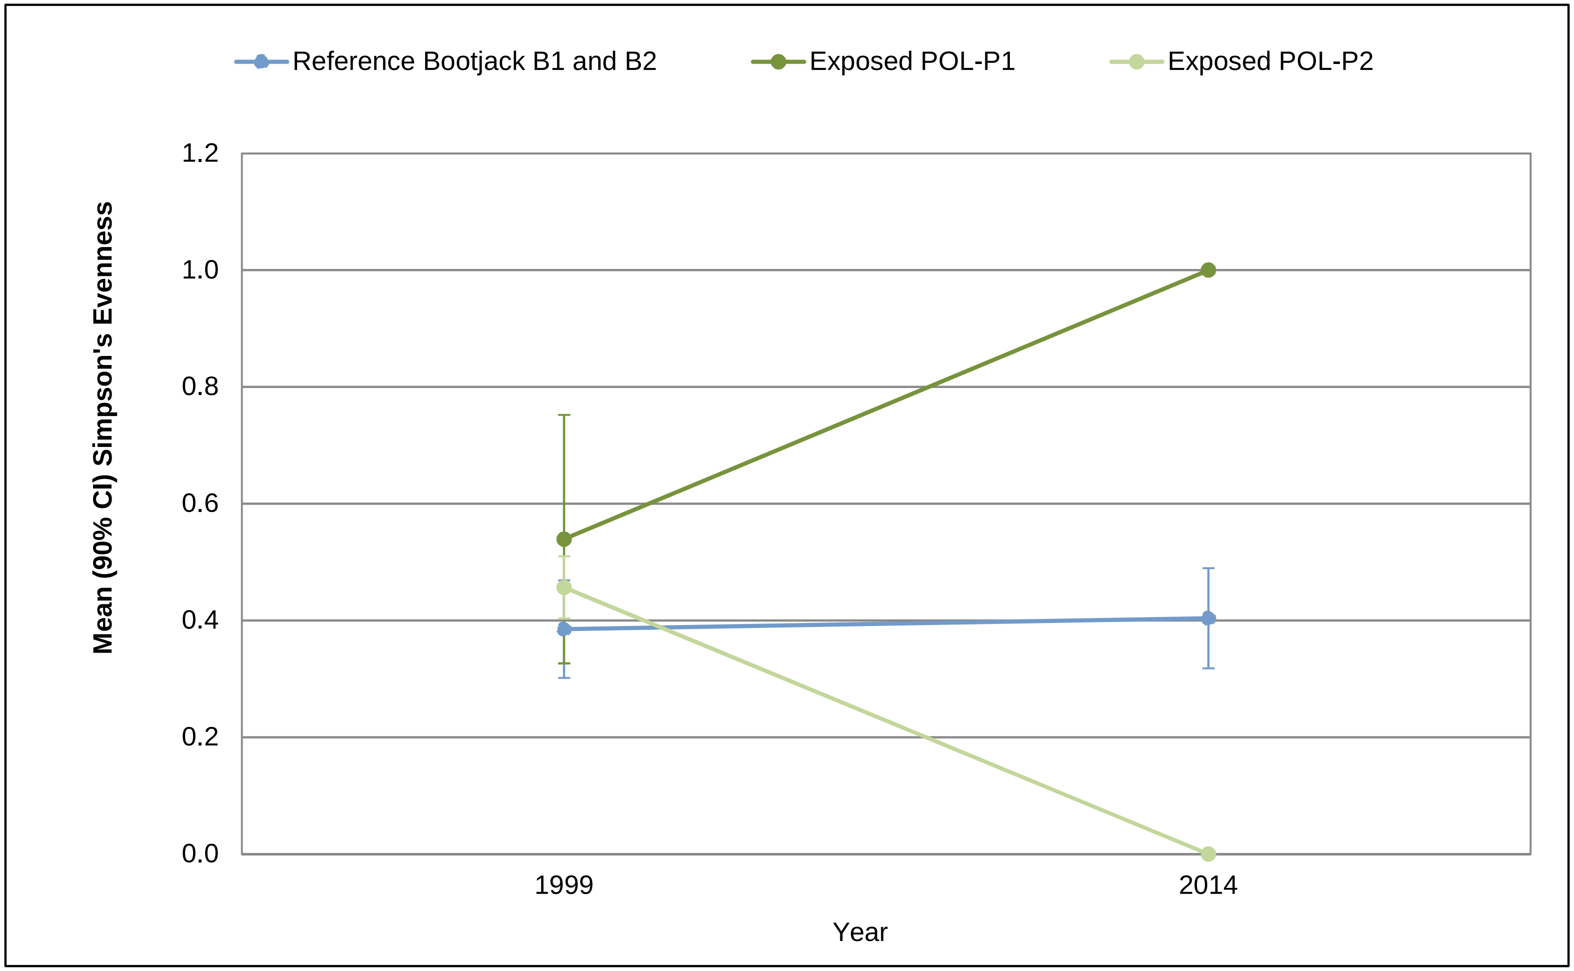

Figure 6.13: Before-After; Control-Impact (BACI) Analysis of effects on Simpson's Evenness, Polley Lake deep lake areas, Mount Polley Mine, 2014. Dashed lines indicate slopes that were not significantly different from reference.

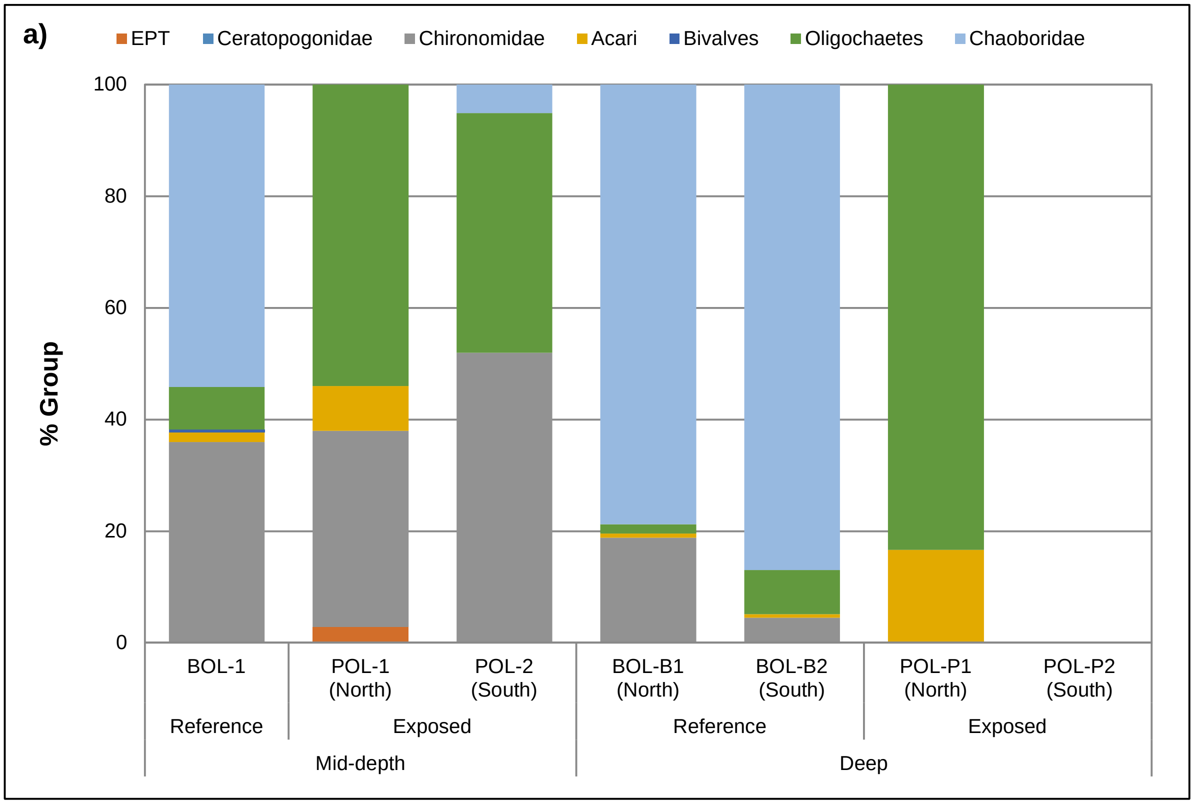

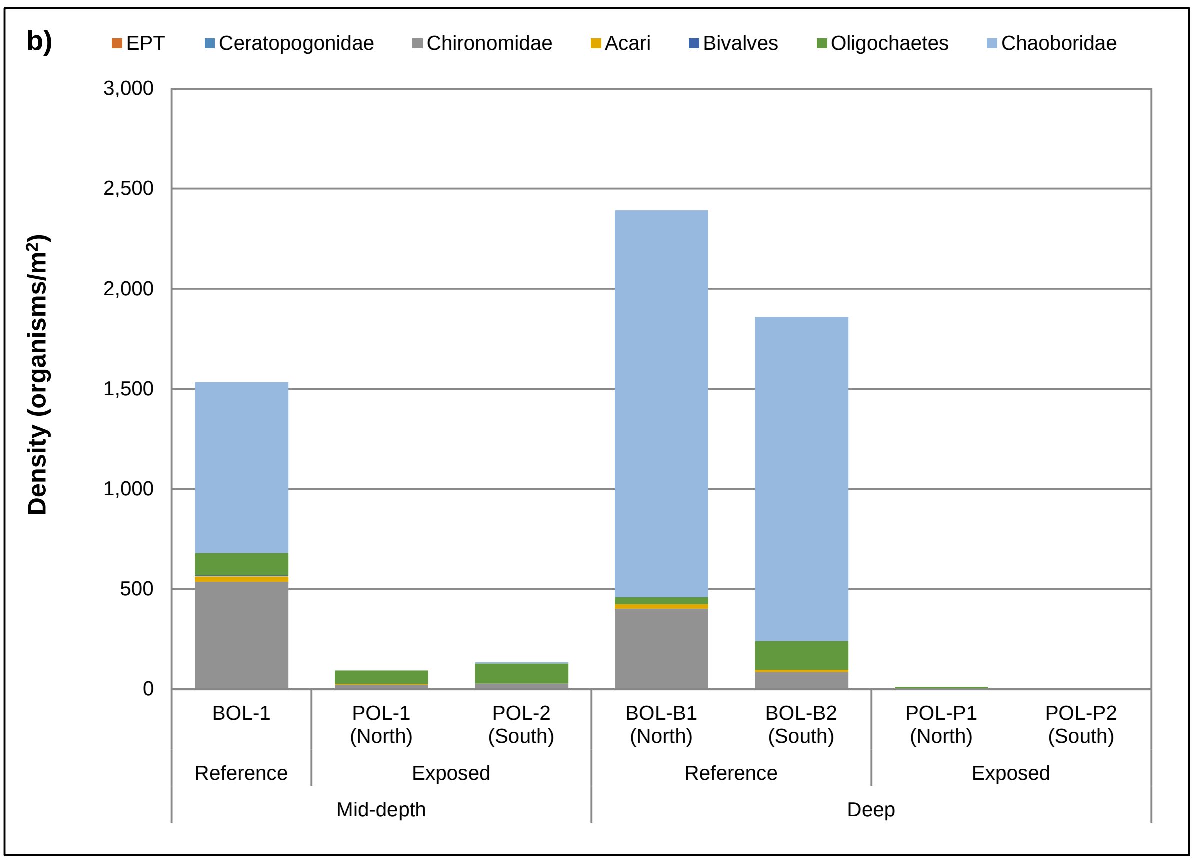

Figure 6.15: Relative mean proportions (a) and mean density (b) of major benthic invertebrate groups, Polley and Bootjack Lake mid-depth and deep sampling areas, Mount Polley Mine, 2014.

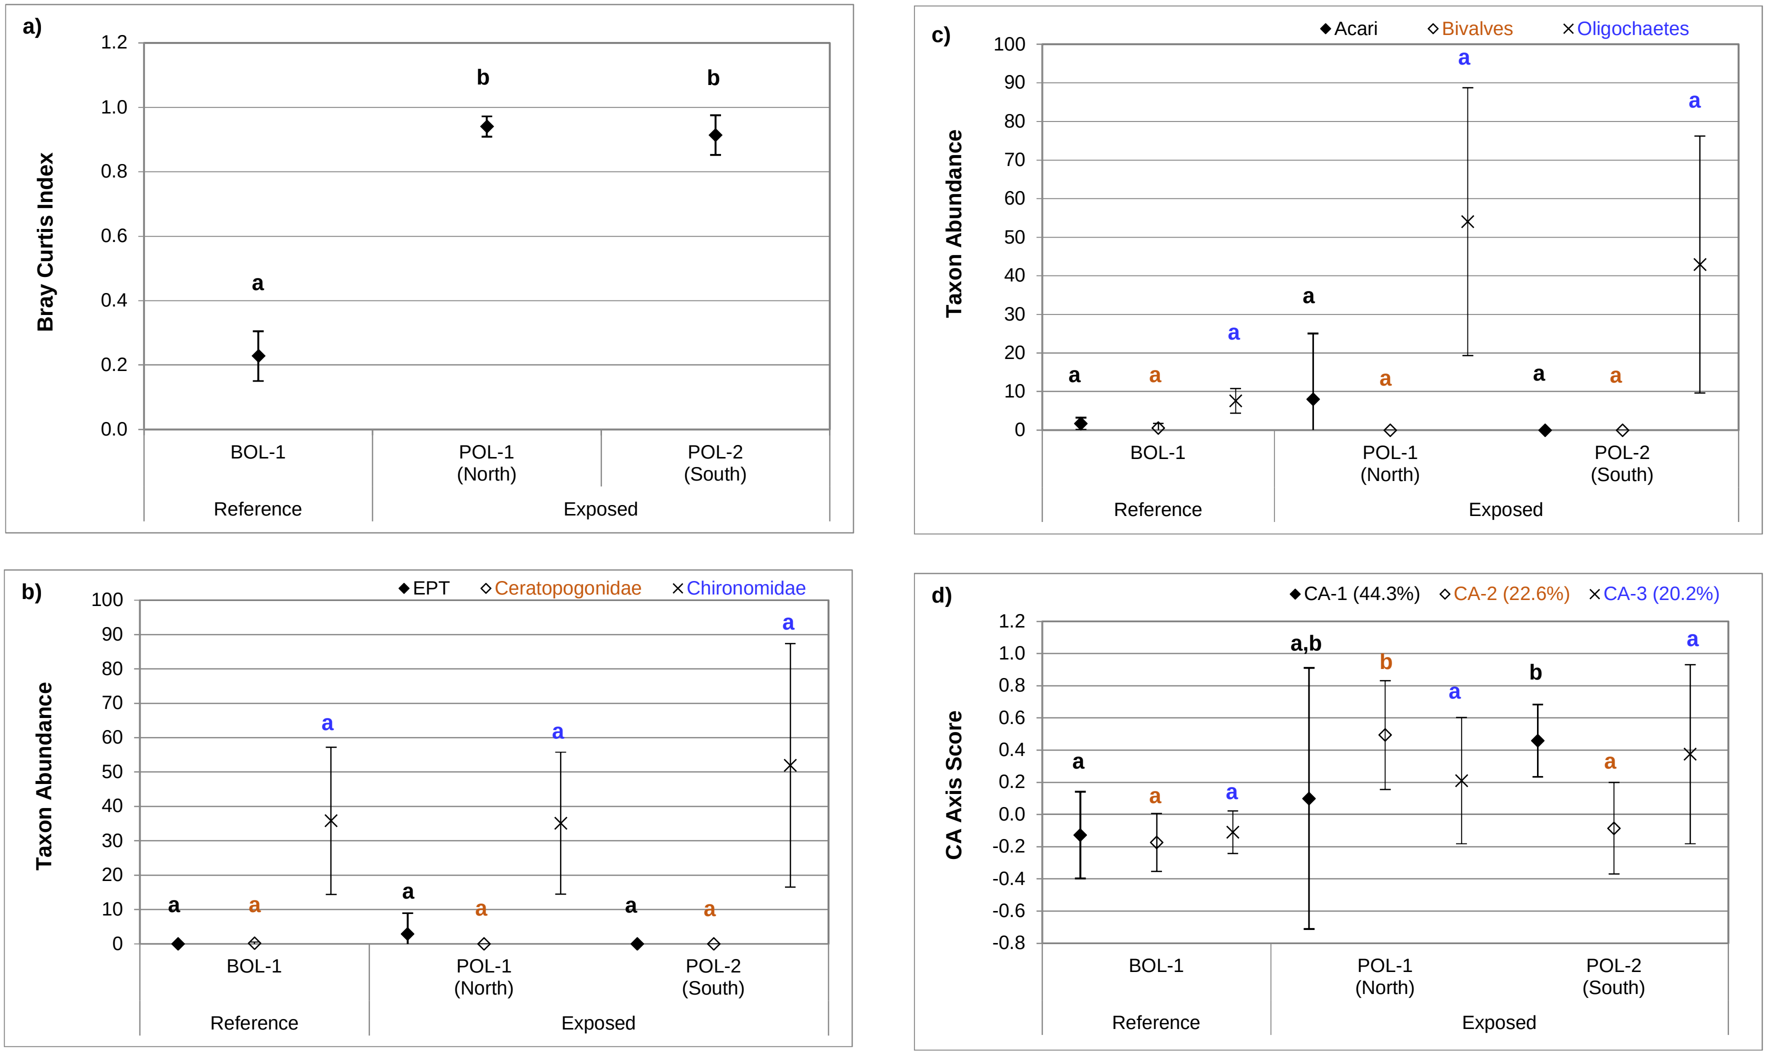

Figure 6.16: Comparison of a) Bray Curtis Index, b) percent Acari, Bivalves and Oligochaetes, c) percent EPT, Ceratopogonidae and Chironomidae and d) CA Axis Score, Mount Polley Mine, 2014. Bootjack and Polley Lake mid-depth area comparisons. Data represents area means and 90% confidence intervals. Different letters above data points indicate areas that were significantly different ($p < 0.1$).

BACI evaluation indicated some differences in how Polley Lake and Bootjack Lake (reference) benthic community composition changed from 1999 to 2014 (Figure 6.17; Appendix Table G.8). Most meaningful was the greater increase in Bray-Curtis distance relative to the 1999 Polley Lake median at P1 than the Bootjack Lake reference (Figure 6.17), indicating an effect on benthic community composition. As previously indicated, community differences detected by the BC index are non-directional and not necessarily related to chemical exposure; however, examination of community composition indicated a greater increase in the relative proportion of oligochaetes at area P1 compared to reference (Figure 6.17). Oligochaetes are pollution tolerant organisms (e.g., Barbour et al. 1999) and community dominance by oligochaetes is typically considered indicative of environmental degradation. Statistically significant interactions were also observed on all three Correspondence Analysis (CA) axes, with CA Axis 1 (30.7% of community variance) essentially detecting the change in the relative abundance of oligochaetes discussed above. CA axis 2 (18.3% of community variance) mainly captured a temporal change in community composition at the reference area, whereas CA Axis 3 scores (14.9% of community variance) increased at P1 while decreasing at reference (Figure 6.17), indicating a notable change in the P1 benthic community from good representation by the chironomids *Protanypus* and *Einfeldia* and the naidid worm *Vejdovskyella* in 1999 to the absence of these taxa in 2014 (Appendix Table G.13; Appendix Figure G.2). Conversely, Bootjack Lake (reference) stations were more likely to be dominated by other chironomids (*Synorthocladius*, *Tanytarsus*, *Cricotopus*, *Sergentia*), and immature tubificids with hair chaetae (Appendix Table G.13; Appendix Figure G.2).

6.6 Correlation Analysis

Correlation analysis was conducted between the biological endpoints (sediment toxicity test and benthic invertebrate community endpoints) and dissolved oxygen, specific conductance, percent fines, sediment TOC content, sediment concentrations of POIs, IPs, PCA axes and selective copper extracts for the mid-depth areas (Table 6.7) and the deep areas (Table 6.8). The only relationship between any of the toxicity test endpoints and the sediment physical/chemical measures was a weak negative correlation between the relative growth of *H. azteca* and carbonate copper (Tables 6.7 and 6.8; Appendix Figure I.4). Given that no significant reduction in *H. azteca* growth was observed relative to concurrent laboratory controls and both references (Section 6.4), this correlation may not be indicative of cause. Overall, the limited number of correlations is perhaps not surprising as the chemical impact on Polley Lake sediment was generally modest and

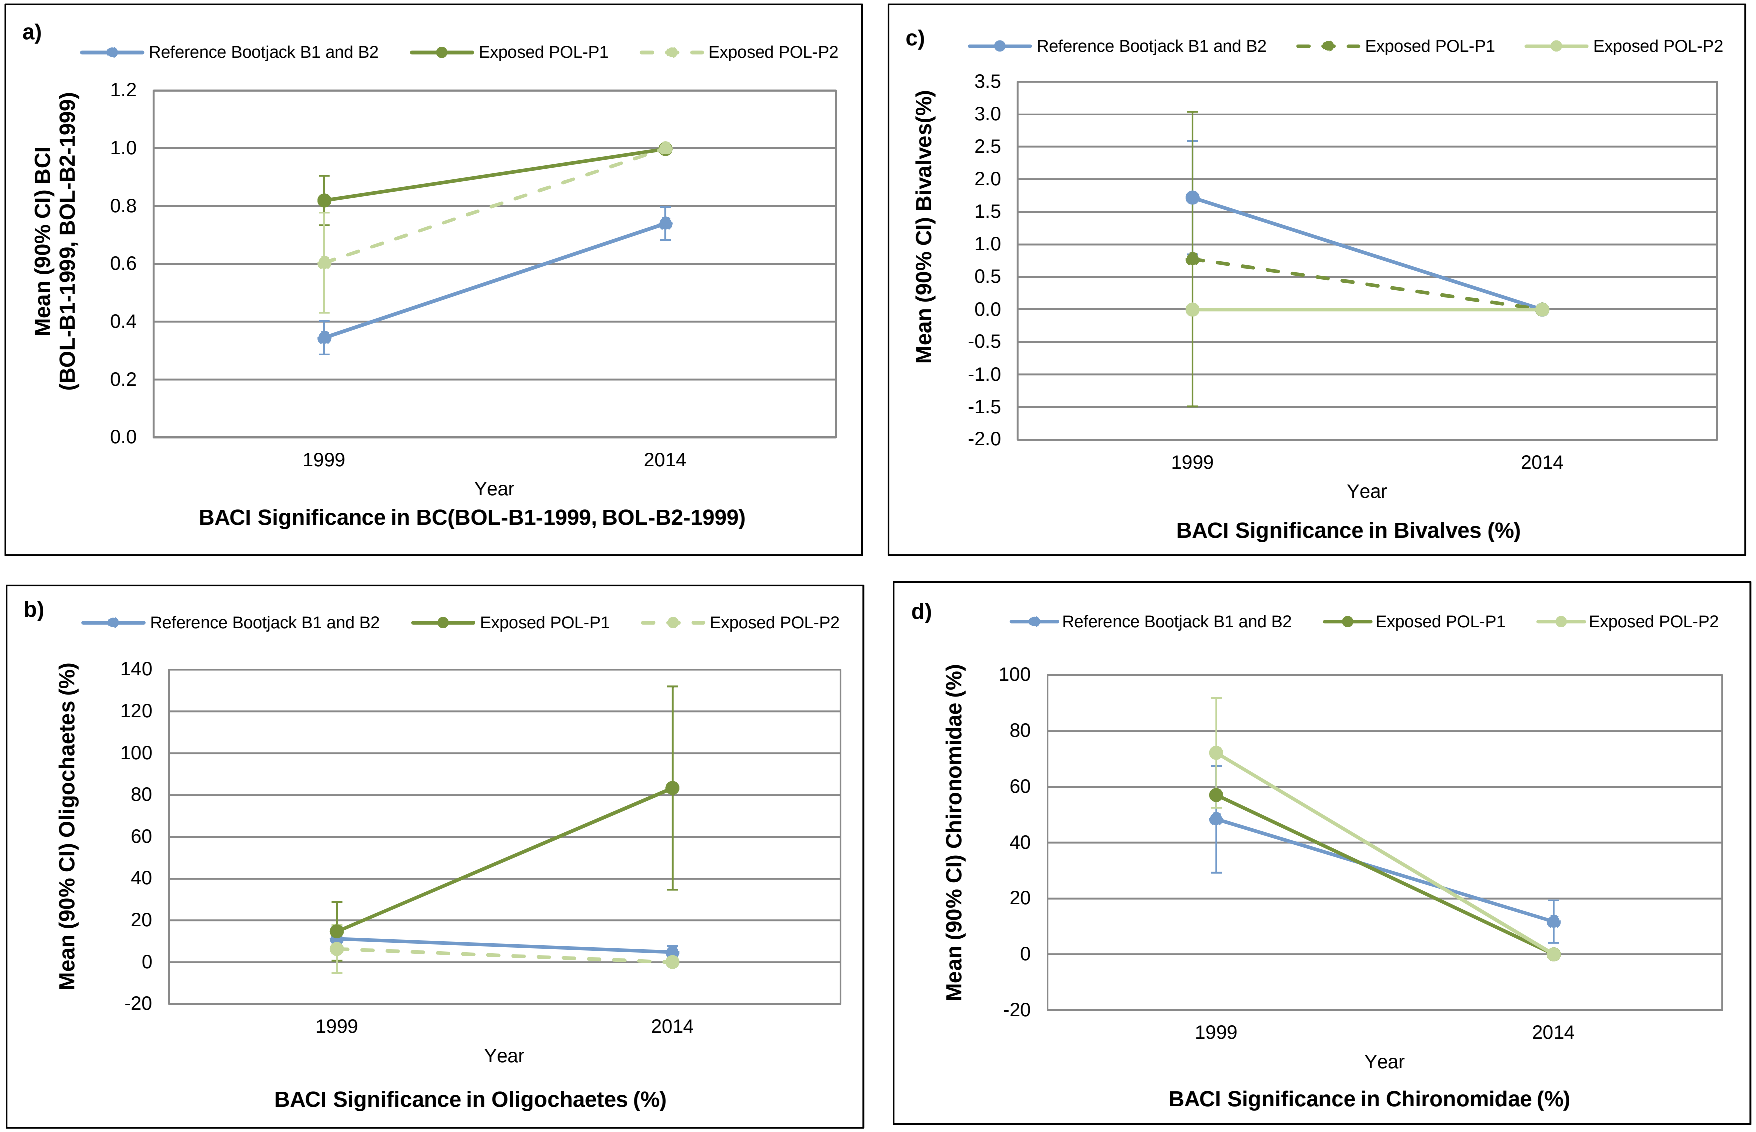

Figure 6.17: Before-After; Control-Impact (BACI) Analysis of Effects on a) Bray Curtis Index (BCI), b) percent Oligochaetes, c) percent Bivalves and d) percent Chironomidae, Polley Lake deep areas, Mount Polley Mine, 2014. Significant correlation; p-value < 0.0001 (Bonferroni corrected p-value for 408 comparisons among Table 6.7 and Appendix Table I.1).

Correlation scatterplot inspected; p <0.01.

[1] Values < method detection limit (MDL) were used at the MDL for calculations. Normalized survival and growth are relative to corresponding laboratory controls.

NA = Correlation was not performed between these two parameters.

Note: n=15 for all correlations.

Table 6.8: Spearman's Rank Correlation results for correlation of toxicity test results and benthic invertebrate community metrics versus water in-situ measures, sediment physical characteristics, parameters of interest, indicator parameters, PCA axes scores, copper extracts (all in < 2mm sediment fraction) in Polley and Bootjack Lake deep sampling areas, Mount Polley Mine, 2014[1].

Significant correlation; p-value < 0.0001 (Bonferroni corrected p-value for 336 comparisons among Table 6.8 and Appendix Table I.2).

Correlation scatterplot inspected; p <0.01.

[1] Values < method detection limit (MDL) were used at the MDL for calculations. Normalized survival and growth are relative to corresponding laboratory controls.

NA = Correlation was not performed between these two parameters.

Note: n=12 for all correlations.

responses in toxicity tests were limited to a slight reduction in survival of *C. dilutus* at area POL-2 (the south side of Polley Lake).

Benthic invertebrate density was positively related to dissolved oxygen and negatively related to specific conductance at the mid-depth areas at the Bonferroni-adjusted p-level (Table 6.7). The former is consistent with low dissolved oxygen at the time of sample collection. No relationships between benthic invertebrate community metrics and sediment chemistry were observed at the mid-depth areas at the Bonferroni-adjusted p-level (Table 6.7). Nine significant correlations were observed in the deep basins at the Bonferroni-adjusted p-level. Percent Chironomidae and CA-axis-1 (mainly representing the oligochaete worm *Lumbriculus*) were correlated with dissolved oxygen (positively and negatively, respectively), suggesting that the low dissolved oxygen observed in Polley Lake favours *Lumbriculus* over Chironomidae. Density, number of taxa and percent Chironomidae were all negatively correlated with specific conductance (Table 6.7), which represents a generic measure of the influence of the dam failure on water quality (i.e., represents higher combined ion concentration). Lastly, a positive correlation between Bray-Curtis dissimilarity and titanium, a negative correlation between percent chironomidae (non-biting midges) and arsenic, and positive correlation between CA axis 2 (which represents lower relative abundance of Chaoborus and higher relative abundance of the naidid *Vejdovskyella* and the chironomid *Einfeldia*) and concentrations of calcium and sodium were observed (Table 6.8; Appendix Figure I.5). At the $p<0.01$ level of significance, a number of additional relationships were apparent (Tables 6.7 and 6.8; Appendix Figure I.6). Although correlation does not necessarily indicate cause, taken together, the relationships observed in the two datasets indicate benthic invertebrate density and/or taxon richness were positively correlated with dissolved oxygen, sediment TOC and negatively correlated with specific a number of POIs and IPs – copper, iron and organic copper at the mid-depth areas and arsenic, copper, iron, most IPs, and copper in the easily reducible and organic phases in the basins. In the basins, both density and number of taxa were also positively correlated with sediment PCA axis 1, which represents concentrations of the POIs and IPs in the negative direction (Figure 6.3). Similarly, Bray-Curtis index of dissimilarity was positively correlated with a number of POIs, IPs and selective extracts of copper (Tables 6.7 and 6.8).

6.7 Data Integration, Summary and Spatial Extent

Sediment collected from Polley Lake following the dam failure was characterized by concentrations of copper greater than SQG PELs and pre-event concentrations and concentrations of arsenic, iron, and zinc greater than TELs and pre-event concentrations.

Copper concentrations at mid-depth areas were similar to pre-event concentrations, but concentrations in the deeper basins were higher than PELs and pre-event concentrations. Sediment geochemical evaluations indicated that, for most POIs and IPs, concentrations were mostly in the residual phase, a fraction that is not considered mobile or biologically available. However, copper was a notable exception, with the majority occurring in the "organic" phase (which appears to be mineral), and with concentrations in the exchangeable, carbonate and easily reducible phases greater than reference. Separate integrated consideration of mineralogy, sequential extraction results and mineral solubility indicates that these forms would not be mobile under environmentally realistic conditions (SRK 2015).

Sediment stratigraphy evaluation indicated that copper was elevated at the south basin at a depth of 6 to 10 cm below surface, indicating heterogeneous intrusion rather than surface influence (settling). Pore-water evaluation indicated some locally elevated metal concentrations at interfaces of mine-derived materials and native sediment. Failure-affected sediments were generally oxidizing, with sediment becoming more reducing with depth (sub-oxic but not sulphidic). Sediments were likely sufficiently reducing to drive reductive dissolution of iron oxides, but because mine-derived material is mostly mineral, this may not result in significant metal mobilization. This is consistent with separate evaluation of potential post-depositional mobility, which indicated very low risk of metal mobilization under reducing conditions (SRK 2015).

Sediment toxicity testing indicated no adverse effect to *H. azteca*, reduced survival of *C. dilutus* at one location (64%), and no effect on growth of *C. dilutus*. The benthic invertebrate community of Polley Lake had lower density and taxon richness than the reference lake (Bootjack Lake). Polley Lake density and taxon richness were within the range documented in some baseline studies, but below those documented in 1999 (the only pre-event sampling with full taxonomic data available). There were no benthic organisms at the south basin of Polley Lake, indicating an unequivocal impact. Benthic invertebrate community composition at the Polley Lake north basin differed dramatically from 1999, with greater proportional representation of oligochaetes and lower proportional representation of Chironomidae, whereas a similar difference was not observed at reference. As oligochaetes are pollution tolerant organisms, this suggests an impact to benthic invertebrate community composition.

Correlation analysis indicated few significant relationships between the toxicity tests endpoints and sediment physical/chemical conditions, which is consistent with limited biological response. Correlation analysis indicated significant relationships between several benthic invertebrate endpoints and TOC content and concentrations of POIs and IPs – in general, there were indications that benthic invertebrate density and taxon richness decreased and Bray-Curtis index of dissimilarity increased with lower TOC content and higher POI and IP concentrations, which suggests a failure-related effect on these metrics. A number of supporting benthic invertebrate community metrics (e.g., percent oligochaete worms and CA axes) showed similar relationships with POIs and IPs.

Overall, an impact of the dam failure was evident in sediment quality of Polley Lake. Copper represents the analyte of greatest concern, both with respect to its absolute concentration relative to guidelines and its geochemical partitioning. Sediment stratigraphic assessment indicated heterogeneous intrusion of mine-derived material and some evidence of metal mobility at interface locations due to reductive dissolution of oxidized mine-derived material. Separate evaluation of potential post-depositional mobility indicated very low risk of metal mobilization under reducing conditions (SRK 2015). Sediment toxicity testing indicated that response was restricted to a reduction in survival of *C. dilutus* at the Polley Lake south deep basin (Area P2), which was also the area of highest copper in potentially mobile phases (fractions 1 to 3). The benthic invertebrate community of Polley Lake had reduced density, taxon richness and some compositional differences relative to Bootjack Lake reference samples and significant relationships to TOC and the POIs and IPs suggests a failure-related effect on these metrics. Given the limited toxicity, it is likely that observed effects on the benthic invertebrate community are more physical (i.e., smothering and low TOC) than chemical. The influence of the dam failure was detectable throughout Polley Lake, but, as might be expected, was more substantial at the south side of the lake.

7.0 QUESNEL LAKE - LITTORAL

Sediment quality impact characterization in the littoral zone of Quesnel Lake included sediment chemistry, sediment geochemical characterization, sediment toxicity testing, and benthic invertebrate community characterization (Table 4.1; Figure 4.4). Data Quality Assessment (DQA; Appendix C with supporting data in Appendix J) indicated that sediment quality data, toxicity test results and benthic invertebrate community data were of good quality and can therefore be used in the sediment quality impact characterization.

7.1 Sediment Physical and Chemical Characterization

Surficial sediment (top 5 cm) within the near-field littoral areas of Quesnel Lake was composed of a mixture of light grey or tan coloured fines, very fine sand (orange and black in colour), and varying amounts of organic matter and woody debris. At the near-field area closest to the mouth of Hazeltine Creek (LNF1), sediment was generally composed entirely of light grey and tan coloured fines with moderate amounts of woody debris, while sediment at the second near-field area (LNF2) was composed of a layer of light grey or tan coloured fines over either hard packed fine sand or a considerable layer of fine organic matter mixed with grey fines. Sediment samples from the second near-field area (LNF2) had a sulphurous odour associated with the layer of fine organic matter that suggested anoxic conditions. Samples from all other littoral sampling areas in Quesnel Lake (reference, far-field, and far-far-field) were generally composed of medium or dark brown fines mixed with varying amounts of sand, organic or woody debris, and aquatic macrophytes (mainly Canadian waterweed; *Elodea canadensis*).

Sediment at the four exposed areas and two reference areas in the littoral zone of Quesnel Lake was predominantly silt and sand (Table 7.1; Appendix Table E.45). Sediment at LNF2 (the near-field area located to the south of the Hazeltine Creek mouth, where scour material flowed through the woods; Figure 4.4) had a higher proportion of silt and clay than all other areas (Table 7.1). Total organic carbon ranged from a low of 0.22% at LNF1 (the mouth of Hazeltine Creek) to 7.36% at LFFF (the far-far-field area located north of Cedar Point near the Town of Likely and the Quesnel Lake outlet; Tables 7.1 and 7.2; Figure 4.4). A spatial pattern of increasing TOC was evident proceeding from area LNF1 to LFFF (Tables 7.1 and 7.2), associated with the input of failure-derived materials low in TOC content. Sediments collected at LNF2 had greater TOC content (2.69%) than those collected at LNF1, possibly due to the presence of the organic debris observed in the field.

Table 7.1: Summary of sediment quality data for Quesnel Lake littoral sampling areas, Mount Polley Mine, 2014. Metals data are based on the < 2mm fraction of sediment [1].

(blue) Value is > TEL. Values shown in bold text also exceed both Reference 95th Percentile values.

(orange) Value is > PEL. Values shown in bold text also exceed both Reference 95th Percentile values.

[1] Data < method detection limit (< MDL) were used at the MDL for the calculation of summary statistics. Summary statistics are reported as < MDL if all the data used in their calculation were < MDL.

[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b); TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.

[3] Reference 95th percentile was calculated using displayed data for the <63µm sediment fraction. The 5th percentile is reported for pH.

Arsenic, copper, iron and manganese were the only analytes with concentrations in Quesnel Lake near-field littoral sediment exposed areas greater than guidelines (PELs in the case of copper and iron, and TELs in the case of arsenic and manganese) and reference concentrations (Tables 7.1 and 7.2; Figure 7.1). However, it is notable that concentrations of arsenic and manganese were similar to or lower than those previously encountered in Hazeltine Creek (Tables 3.2 and 3.3; Tables 5.1 and 5.2). Concentrations of ten additional analytes were present in Quesnel Lake littoral sediment at concentrations more than two times greater than reference concentrations (barium, calcium, mercury, molybdenum, selenium, silver, sodium, strontium, tin and vanadium; Tables 7.3 and 7.4). This list includes the IPs identified for Hazeltine Creek (Section 5.1), with the addition of barium, mercury, selenium, strontium, tin and vanadium. Concentrations of both mercury and selenium were similar to or lower than those previously encountered in Hazeltine Creek (Tables 3.2 and 3.3; Tables 5.1 and 5.2). In accordance with the framework set out in Section 4.0, arsenic, copper, iron and manganese are designated as POIs and barium, calcium, mercury, molybdenum, selenium, silver, sodium, strontium, tin and vanadium are designated as IPs. All POIs identified in the evaluations of Hazeltine Creek and Polley Lake (i.e., arsenic, copper, iron, manganese and nickel; Sections 5 to 6) are considered as part of this characterization of Quesnel Lake littoral sediment.

Principal Components Analysis (PCA) was effective in distinguishing sediments of the near-field exposed areas (LNF1 and LNF2) from other areas primarily on the basis of negative axis 1 scores, indicating finer sediment and higher concentrations of a number of metals (arsenic, barium, beryllium, calcium, cobalt, copper, iron, magnesium, manganese, molybdenum, phosphorus, potassium, silver, sodium, and vanadium; Figure 7.2). With the exception of mercury, selenium, tin and vanadium, this list includes all POIs and IPs identified above and serves to confirm their importance.

Of the four POIs and ten IPs, copper was the most substantially elevated, with concentrations up to approximately 3.7 times the PEL and 24 times reference (Tables 7.1 to 7.4; Figures 7.1 and 7.3). Copper concentration was greatest at areas LNF1 and LNF2 (near-field areas, and was slightly enriched in the <2 mm fraction relative to the <63 µm fraction; Figure 7.1). Concentrations of the other POIs were generally enriched in the <63 µm fraction relative to the <2 mm fraction (Figure 7.1). Concentrations of arsenic, copper, iron and manganese decreased with distance from LNF1 to LFF, but were generally greater at LFFF than at LFF (Figure 7.1), presumably due to the much higher concentration of TOC at LFFF rather than any failure-related influence (similar elevations of chromium, nickel and selenium were also observed at LFFF, presumably for the same

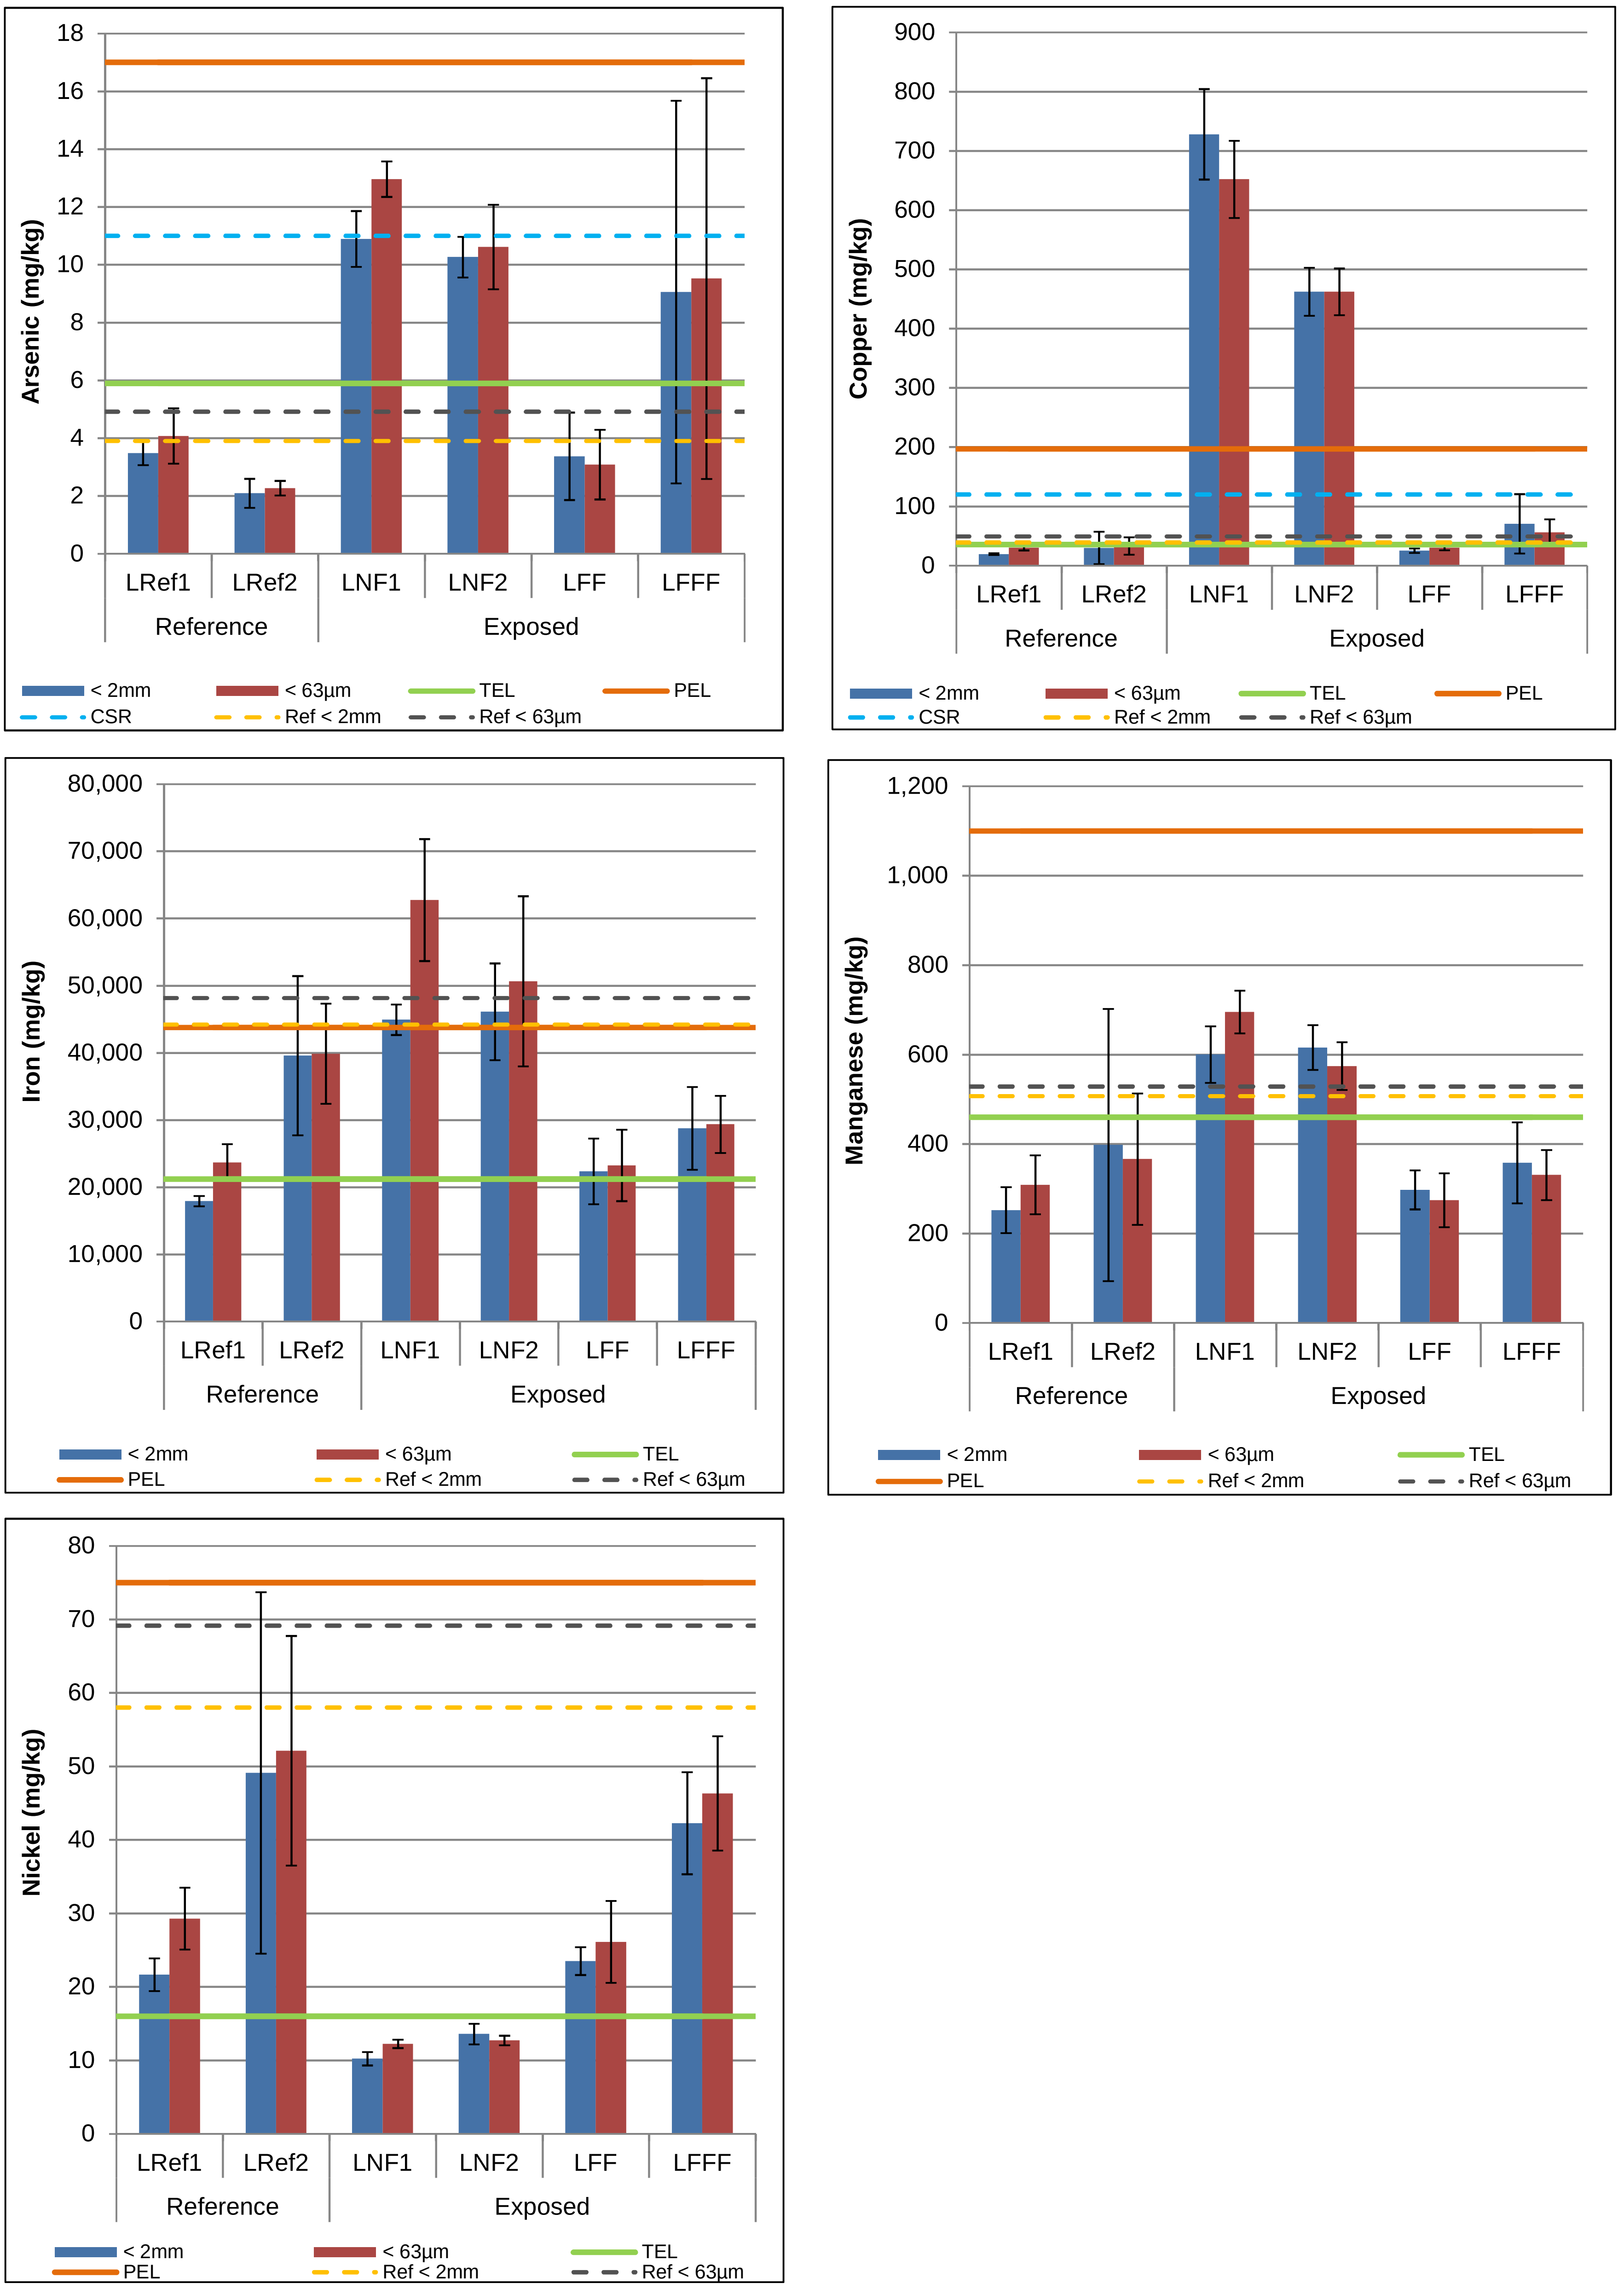

Figure 7.1: Mean metal concentrations (± t*SE) in sediment from Quesnel Lake littoral sampling areas for parameters of interest identified in Quesnel Lake littoral and other sampling areas (Polley Lake), Mount Polley Mine, 2014.

TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level; CSR = Contaminated Sites Regulation - Sensitive; BG = Historic 95th percentile. Ref < 2mm and Ref < 63 µm values were selected as the highest 95th percentile value for an anlalyte in either the LRef1 or LRef2 reference areas for the < 2mm and < 63 µm sediment fractions.

Table 7.3: Ratio of exposed mean to reference mean metal concentrations[1,2] in the < 2mm fraction of sediment from littoral sampling areas of Quesnel Lake, Mount Polley Mine, 2014. Ratios with a value > 2 are highlighted.

[1] The highest mean concentration for each analyte from among the littoral reference areas (LRef1 and LRef2) was used as the reference mean for calculation of the ratio.

[2] Mean values < method detection limit (MDL) were used at the MDL for calculation of exposed/reference ratios.

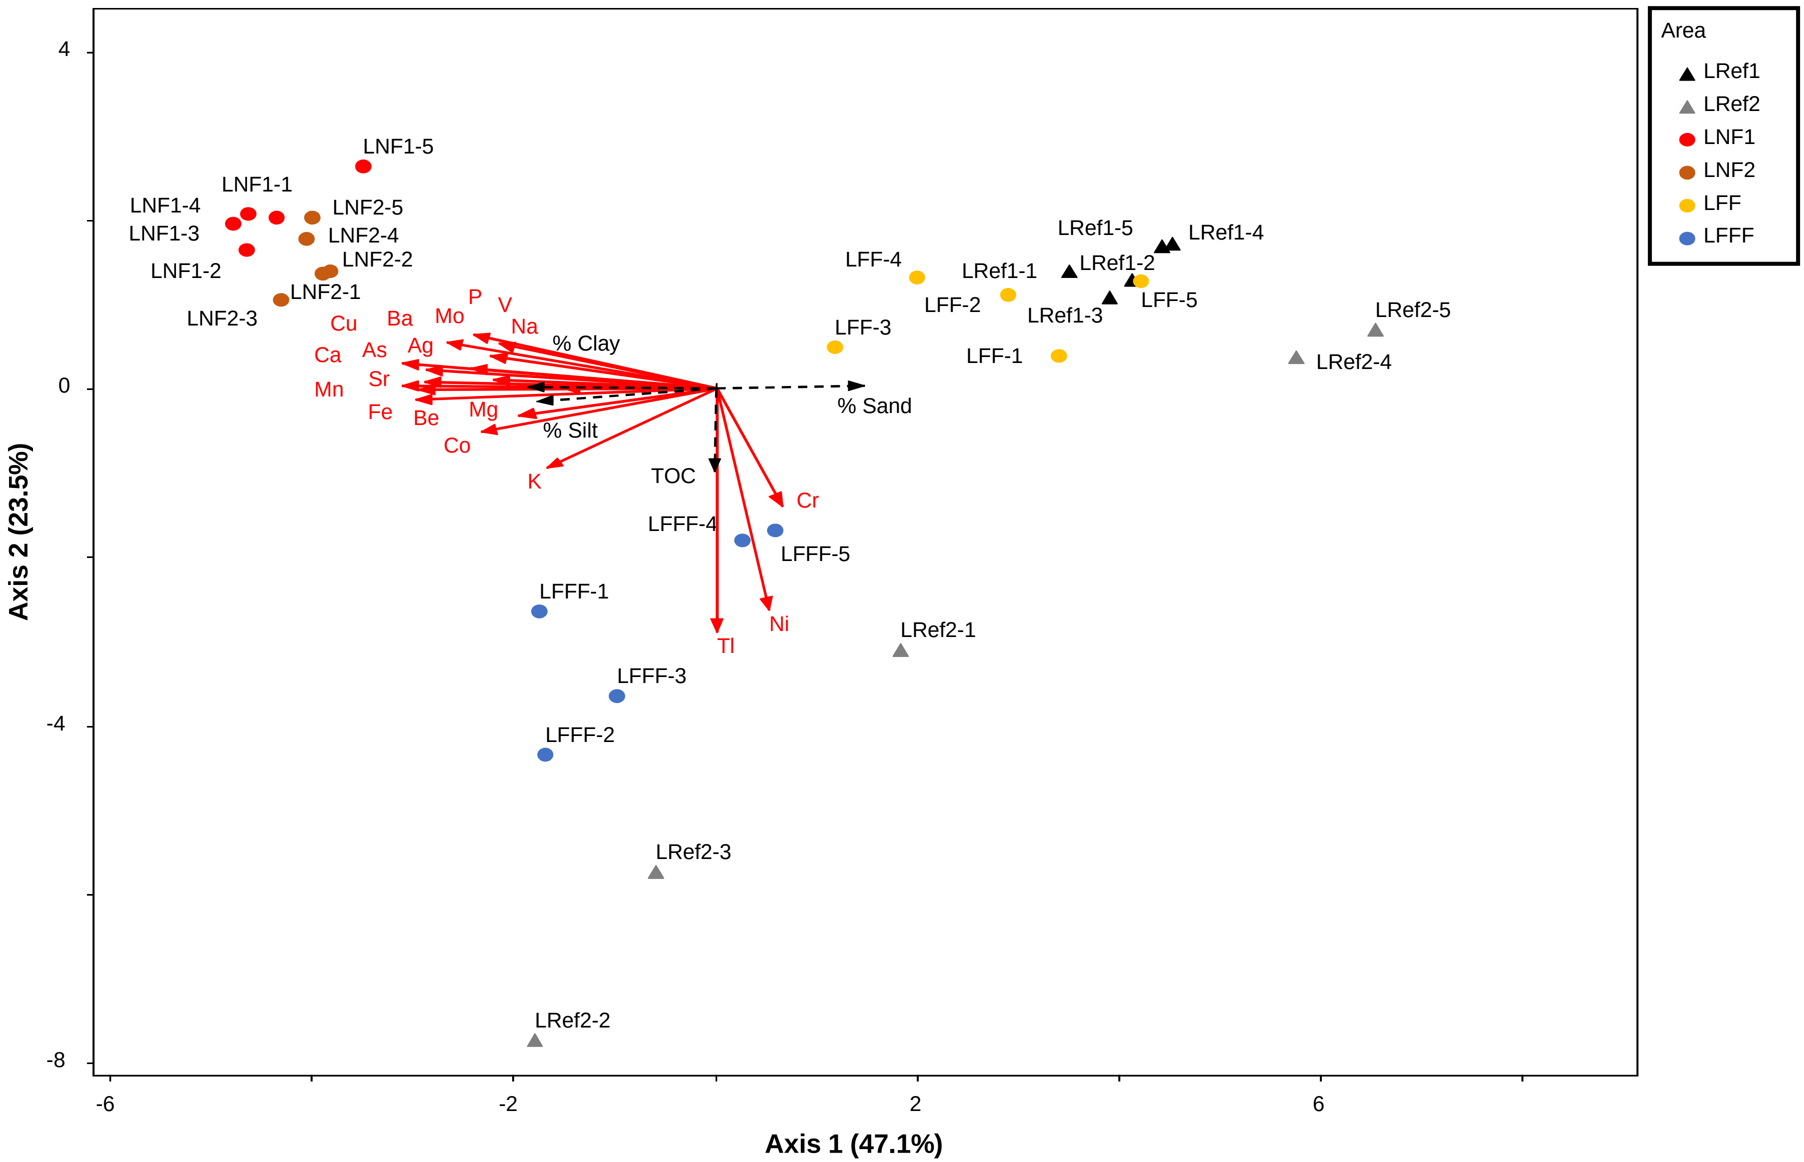

Figure 7.2: Biplot of principal component analysis (PCA) of metal concentrations in sediment (<2 mm fraction) from Quesnel Lake littoral sampling stations, Mount Polley Mine, 2014. Vector length is proportional to the magnitude of direct correlation of metals (solid red vector lines) and indirect correlation of sediment physical characteristics (black dashed vector lines) with PCA values of each axis (Appendix Tables E.47-E.48). Only metals with significant (p-value <0.010) Spearman's correlation and r-values > 0.7 with either axis are displayed, all sediment physical characteristics are displayed [a].

[a] Boron, mercury, and tin were excluded from calculations due to a lack of variability in the data (all values for each analyte were the same), or an incomplete data set.

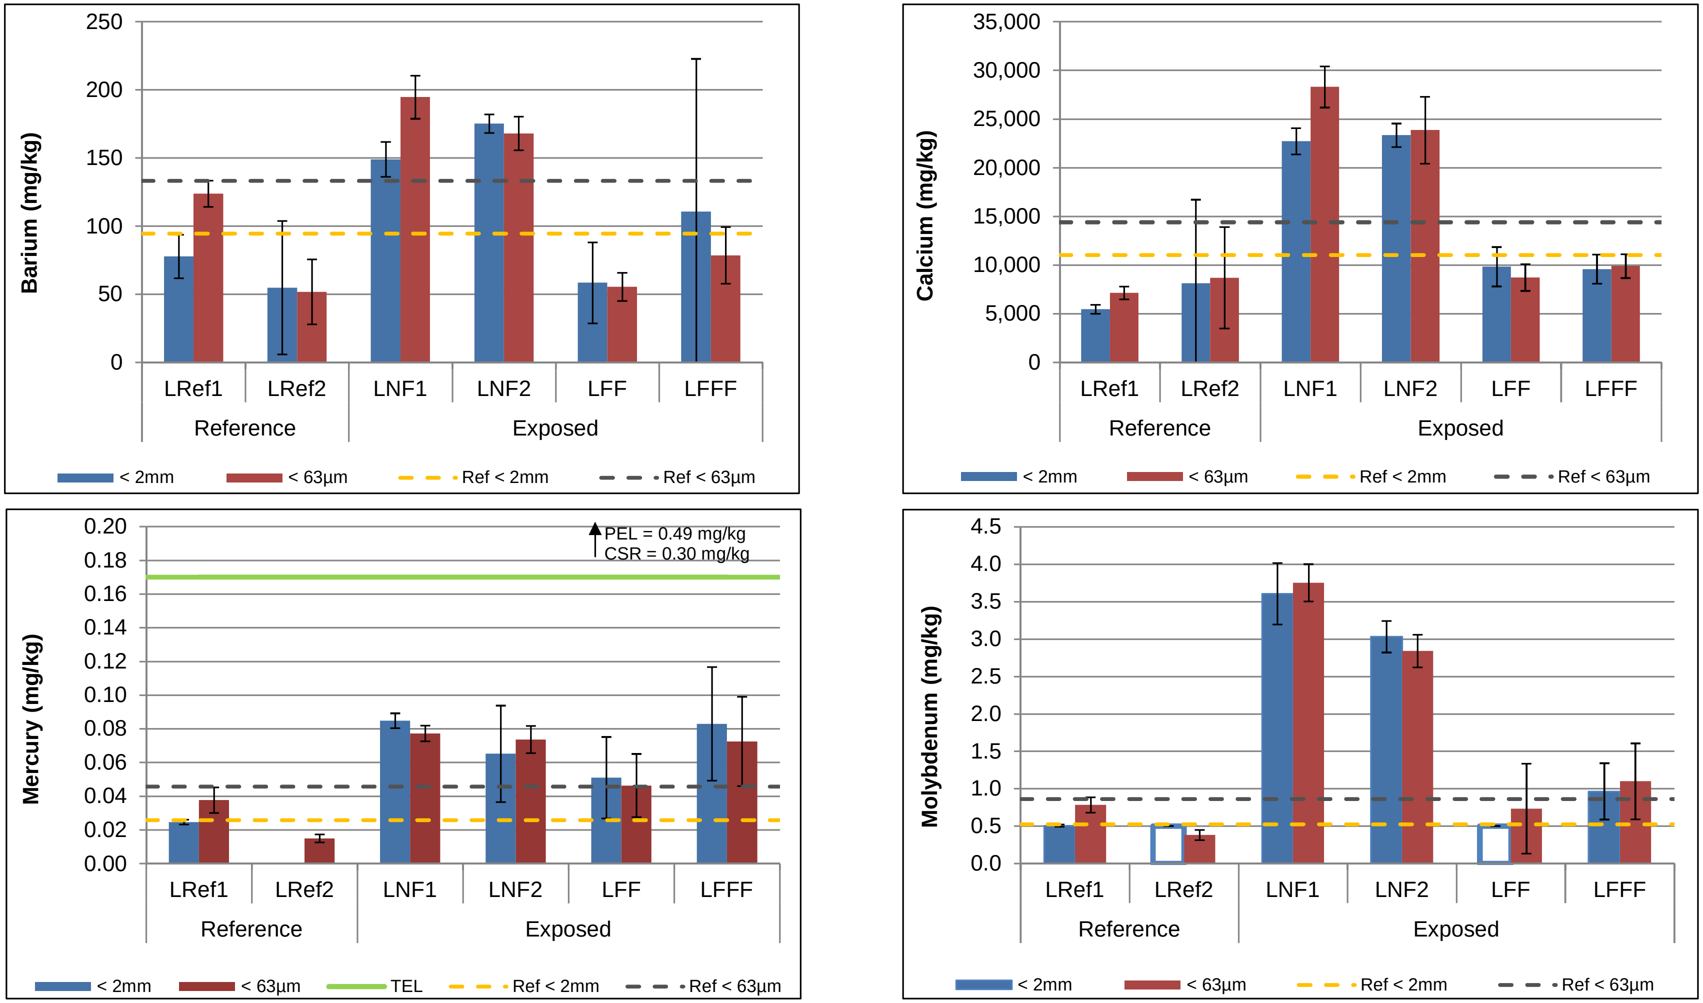

Figure 7.3: Mean metal concentrations (± t*SE) for indicator parameters in sediment from littoral sampling areas in Quesnel Lake, Mount Polley Mine, 2014. Hollow bars indicate all values used to calculate the mean were < the method detection limit.

TEL = Threshold (or Lowest) Effect Level; BG = Historic 95th percentile; CSR = Contaminated Sites Regulation - Sensitive. Ref < 2mm and Ref < 63 µm values were selected as the highest 95th percentile value for an anlalyte in either the LRef1 or LRef2 reference areas for the < 2mm and < 63 µm sediment fractions.

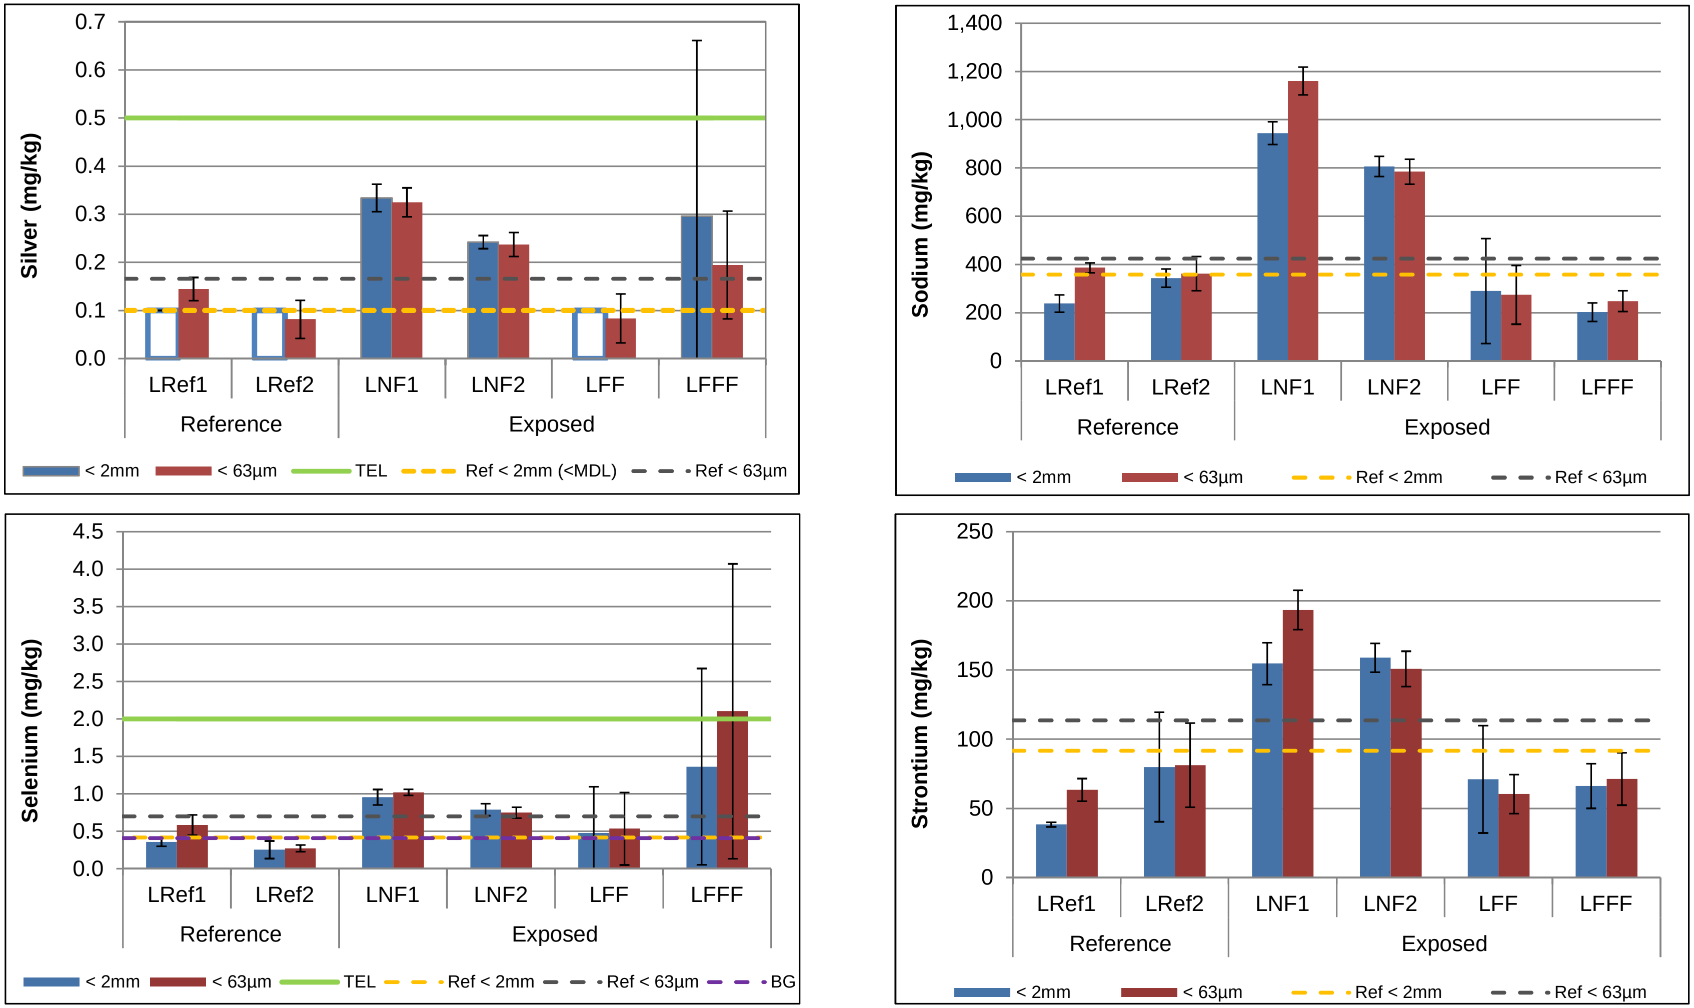

Figure 7.3: Mean metal concentrations (± t*SE) for indicator parameters in sediment from littoral sampling areas in Quesnel Lake, Mount Polley Mine, 2014. Hollow bars indicate all values used to calculate the mean were < the method detection limit.

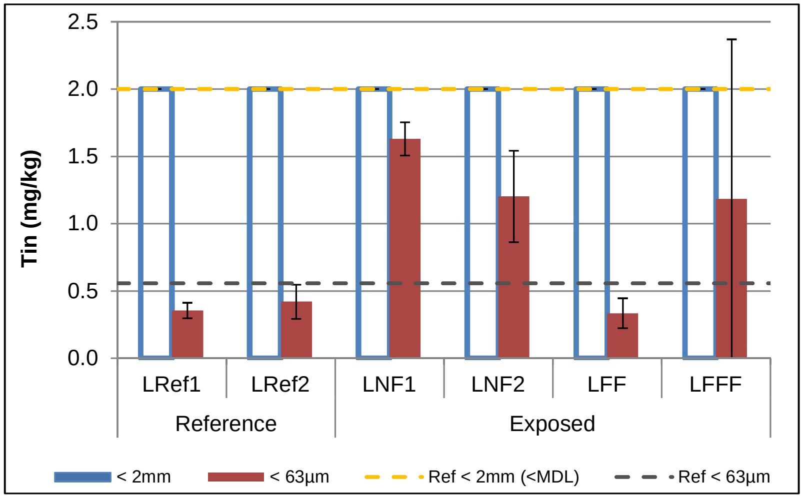
TEL = Threshold (or Lowest) Effect Level; BG = Historic 95th percentile; CSR = Contaminated Sites Regulation - Sensitive. Ref < 2mm and Ref < 63 µm values were selected as the highest 95th percentile value for an anlalyte in either the LRef1 or LRef2 reference areas for the < 2mm and < 63 µm sediment fractions.



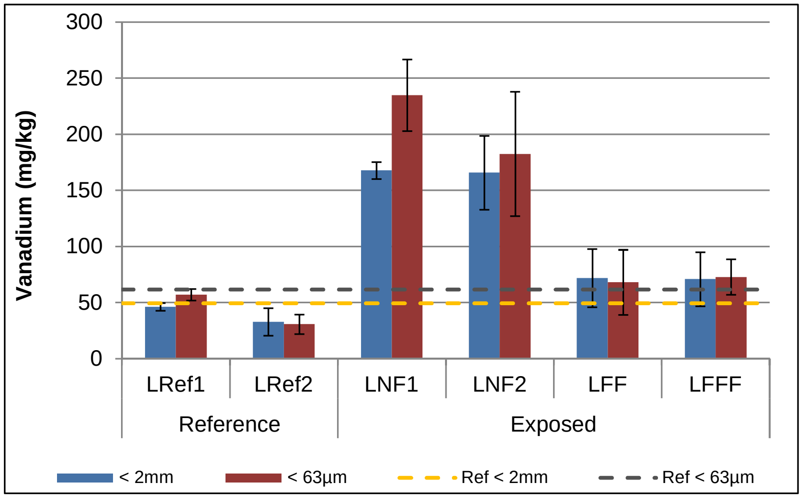


Figure 7.3: Mean metal concentrations (± t*SE) for indicator parameters in sediment from littoral sampling areas in Quesnel Lake, Mount Polley Mine, 2014. Hollow bars indicate all values used to calculate the mean were < the method detection limit.

TEL = Threshold (or Lowest) Effect Level; BG = Historic 95th percentile; CSR = Contaminated Sites Regulation - Sensitive. reason). Concentrations of POIs were below SQG-TELs and/or reference at area LFF (Figure 7.1). Similarly, concentrations of all IPs decreased with distance from LNF1 to LFF, but were generally greater at LFFF than at LFF (Figure 7.3). Concentrations of IPs were generally similar to reference at area LFF (Figure 7.3).

Concentrations of all POIs and most IPs were positively correlated with percent fines (percent silt and clay), and there were no negative correlations with percent fines (Table 7.5; Appendix Figures E.25-E.26). Only two statistically significant relationships were observed with sediment total organic carbon (TOC) content – a positive relationship with nickel and a negative relationship with sodium (Table 7.5; Appendix Figure E.25). Thus, the dominant physical relationship was a positive relationship between concentrations of POIs and IPs and fines.

7.2 Sediment Geochemical Characterization

As previously indicated, there are numerous factors that affect the bioavailability of metals in sediments. While metal concentrations that are below the sediment quality guidelines generally provide a reliable indicator of an absence of effect, sediment quality results that exceed those benchmarks provide a less reliable indication that effects are probable. Geochemical characterization can assist in characterizing the potential mobility and bioavailability of metals associated with mine-influenced sediments.

Selective extractions indicated that concentrations of most POIs and IPs were primarily in the residual phase; that is, they could only be extracted by the strongest acid digest (a combination of concentrated nitric and hydrochloric acid; Table 7.6; Appendix Table E.51; Figure 7.4; Appendix Figures E.27-E.28). As previously discussed, residual metals are unlikely to be mobilized under any conditions that could realistically occur in the environment, nor in interactions with aquatic organisms (i.e., contact with the gill or ingestion) and are therefore considered not biologically available (e.g., Tessier et al. 1979; Campbell and Tessier 1996). Exceptions included copper and molybdenum, which had greatest concentrations of in the “organic” phase (Figure 7.4; Appendix Figures E.27-E.28). As previously discussed (Section 5.2), it is likely that the “organic” phase represents mineral copper. This copper partitioning differed substantially from that observed in reference sediment and far-field sediment, where copper approximately 60% of sediment-associated copper was in residual form (Figure 7.4).

Concentrations of copper in Fractions 1 to 3 (exchangeable + carbonate bound + reducible) at near-field areas exceeded reference (Figure 7.4). However, separate integrated consideration of mineralogy, sequential extraction results and mineral solubility

Table 7.5: Spearman's Rank Correlation results for correlation of concentrations of parameters of interest and indicator parameters (in < 2mm sediment fraction) relative to % fines (silt and clay) and total organic carbon in sediment from Quesnel Lake littoral sampling areas, Mount Polley Mine, 2014 [1].

(blue)	Value is > TEL. Values shown in bold text also exceed both Reference 95th Percentile values.
(orange)	Value is > PEL. Values shown in bold text also exceed both Reference 95th Percentile values.

[1] Data < method detection limit (< MDL) were used at the MDL for the calculation of summary statistics. Summary statistics are reported as < the highest displayed MDL if all the data used in their calculation were < MDL. Summary statistics (mean, t*SE, and maximum) were only calculated for sampling areas with replicate samples (LRef1, LNF1,and LNF2) but not for single composite samples (LRef2, LFF, and LFFF).

[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b); TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.

[3] Displayed reference values are the 95th percentiles of data from reference area LRef1 and are the single values available for reference area LRef2.

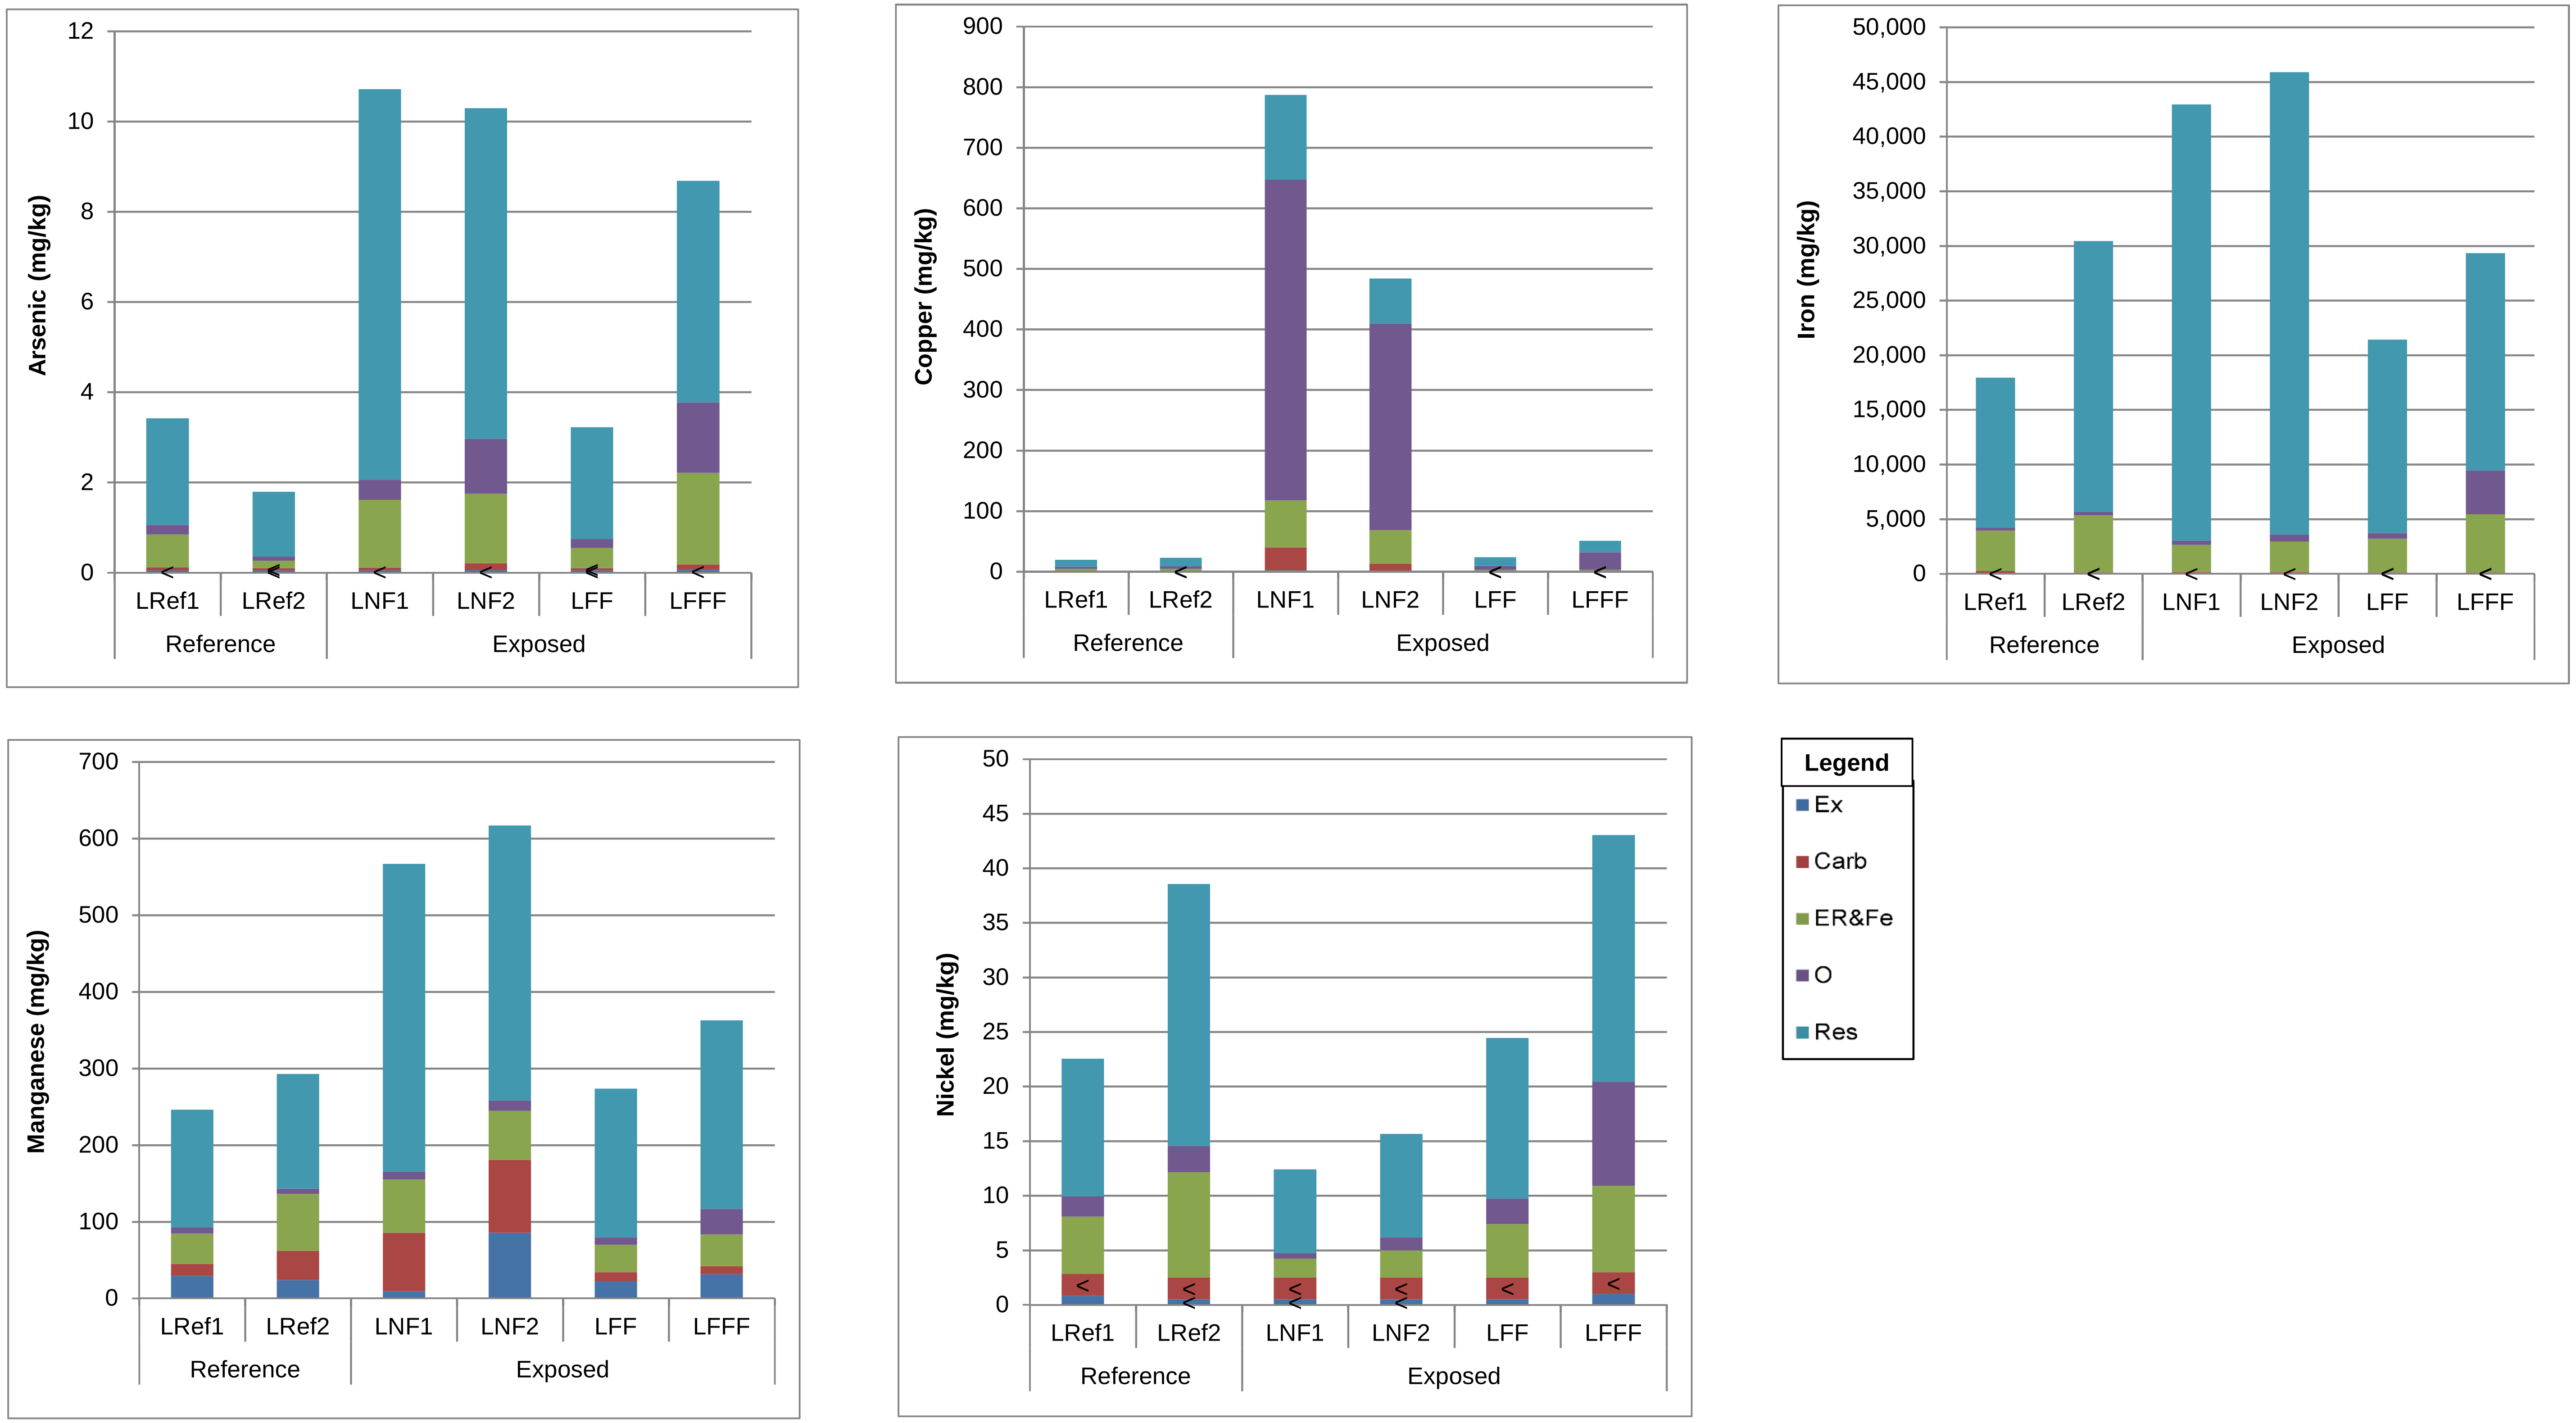

Figure 7.4: Mean concentrations of selectively extracted parameters of interest in sediment from the littoral sampling areas of Quesnel Lake, Mount Polley Mine, 2014. Selective extractions included Exchangeable & Adsorbed Metals (Ex), Carbonate Metals (Carb), Easily Reducible Metals and Iron Oxides (ER&Fe), Organic Bound Metals (O), and Residual Metals (Res).

Values < MDL are indicated with a < symbol. Mean values are plotted for areas with replicate samples (LRef1, LNF1, LNF2), single values are plotted for composite samples (LRef2, LFF, LFFF).

indicates that these forms would not be mobile under environmentally realistic conditions (SRK 2015). Therefore, sediment copper also appears to be present in Polley Lake sediments in forms that are not mobile and this immobility suggests limited concern for aquatic biota.

Shake flask tests indicated low mobility of metals associated with Quesnel Lake littoral sediments, with copper and manganese being the only metals mobilized in shake flask tests to concentrations greater than British Columbia Water Quality Guidelines (BCWQG; Appendix Table E.52; Table 7.7). As manganese was similarly elevated in shake flask tests of one of the reference areas, only copper at near-field areas appeared to be more leachable than reference and to potentially meaningful concentrations. However, as previously stated, BCWQG do not apply to sediment leachates, but are used herein as an indication of low mobility.

Acid-Base accounting results indicated that the potential for acid generation decreased with distance from the influence of the dam failure (Appendix Tables E.12 and E.53). Neutralization potential ratio (NPR; the ratio of neutralization potential to maximum potential acidity) was 10 and 13 at the near-field areas and decreased to 3.8 at the far-field area and 1.1 at the far-far-field area (Appendix Table E.12). NPR greater than 4 indicates no potential for Acid Rock Drainage (ARD; Price 1997). Decreasing NPR with distance from Hazeltine Creek indicates that acid potential associated with the impacted sediments is lower than reference and far-field sediments (i.e., the failure-influenced materials had higher neutralization potential than native sediment).

7.3 Sediment Toxicity

Sediment toxicity testing indicated no instances of significantly reduced survival or growth of the freshwater/brackish water amphipod *Hyalella azteca* relative to concurrent laboratory controls and both references (Figure 7.5; Appendix Table F.1; Appendix Figure F.5). However, a spatial pattern of increasing growth with distance from the mouth of Hazeltine Creek was apparent, likely in association with increasing sediment TOC concentrations (reduced concentrations of POIs could also play a role but do not explain highest growth at the far-far-field area). There were no instances where survival of the freshwater midge *Chironomus dilutus* was significantly reduced relative to concurrent laboratory controls and both references (Figure 7.5; Appendix Table F.1; Appendix Figure F.6). However, examination of absolute survival (non-normalized) indicated low survival at area LNF1 (45%), indicating an apparent, albeit not statistically significant, reduction of survival (Appendix Table F.8). As evident for survival, growth of *C. dilutus* was significantly reduced at area LNF1 relative to laboratory controls and both references, but

Table 7.7: Summary of leachable metals data for sediment from Quesnel Lake littoral sampling areas, Mount Polley Mine, 2014. Data are based on bulk sediment [1]. Only analytes with detectable concentrations are displayed.

[3] Hazardous Waste Regulation (Government of British Columbia 1988)

[4] Displayed reference values are the 95th percentiles of data from reference area LRef1, and are the single values available for reference area LRef2.

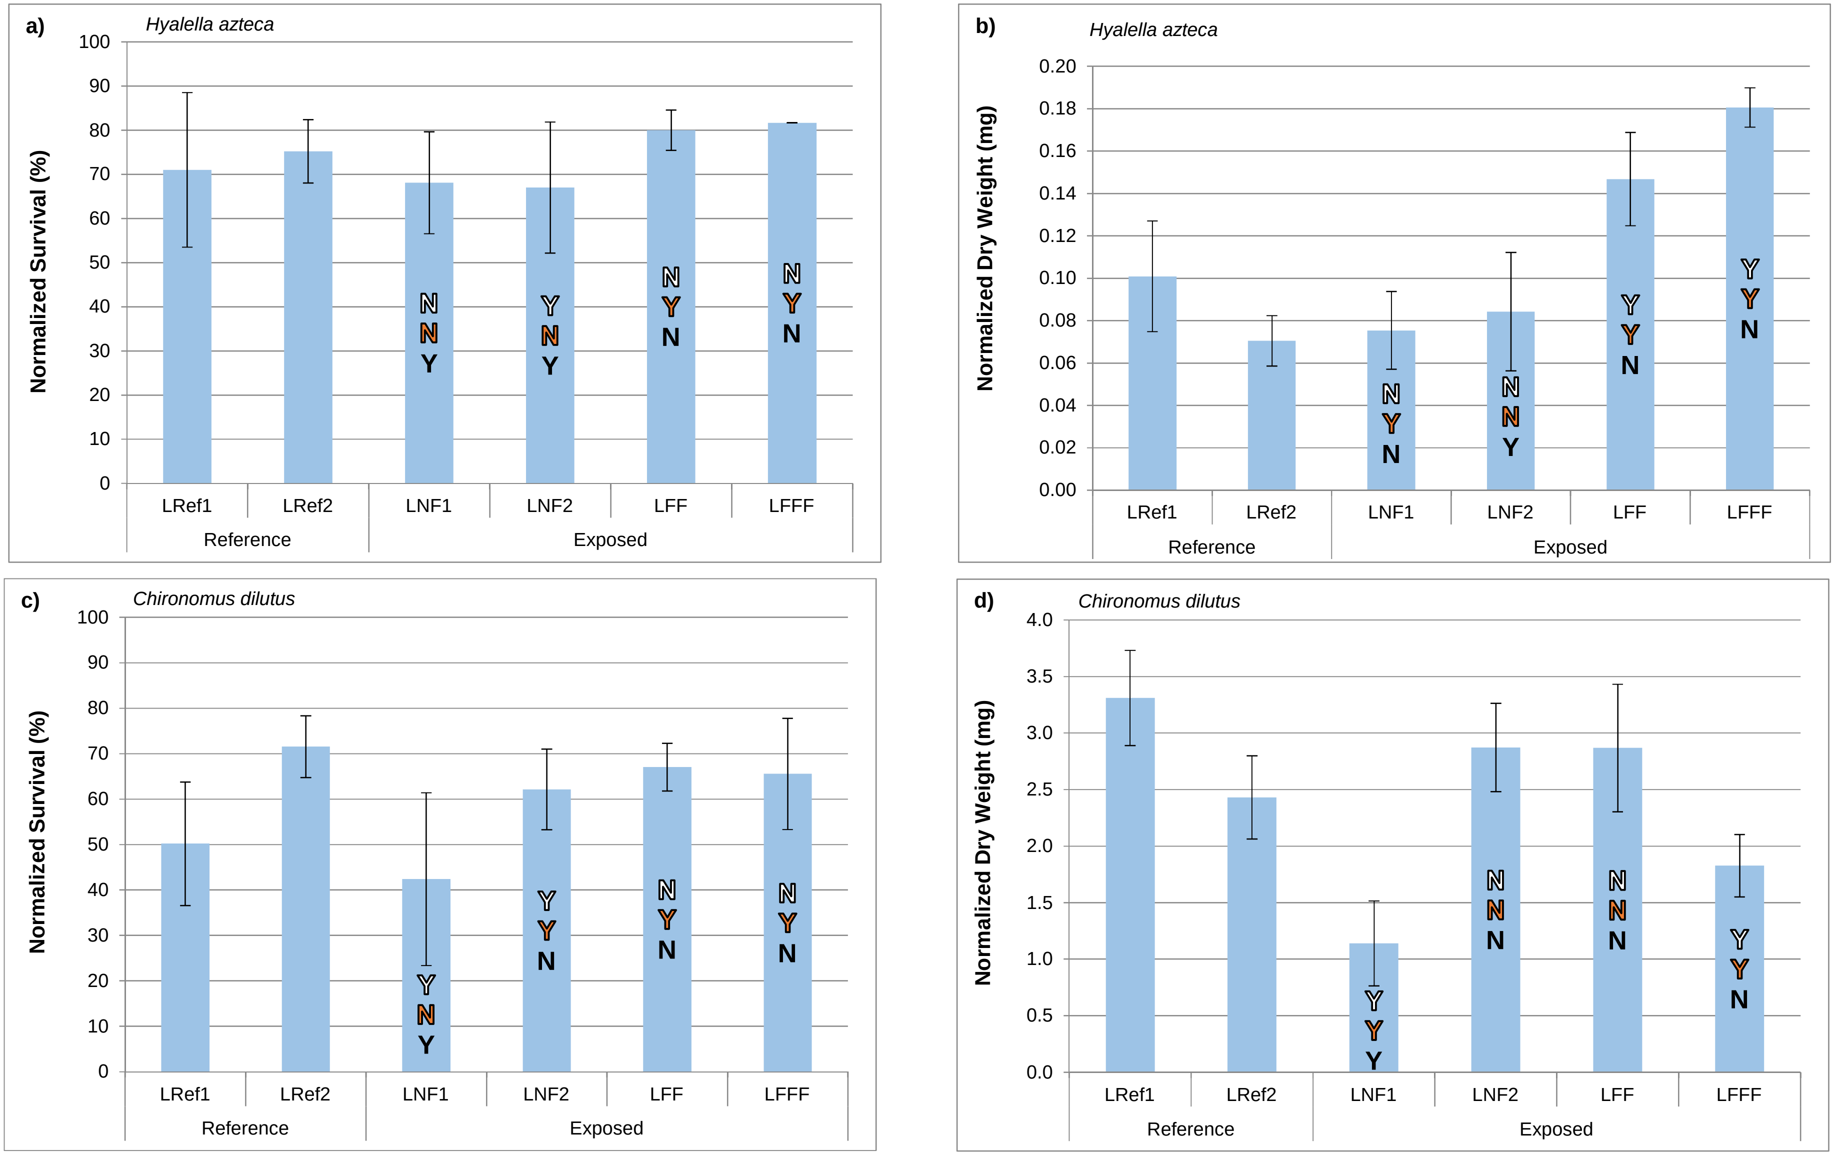

Figure 7.5: Toxicity tests of Quesnel Lake littoral sediment, Mount Polley Mine, 2014. Results for *Hyalella azteca* a) Normalized Survival (%), b) Normalized Dry Weight (mg) and *Chironomus dilutus* c) Normalized Survival (%), d) Normalized Dry Weight (mg). Error bars represent standard deviation. Letters represent significant differences (Y) or no differences (N) between and the Control (Black), Reference 1 (Orange) and Reference 2 (White) (p < 0.05). Control results are not displayed.

not at any other littoral areas (Figure 7.5; Appendix Table F.1). No consistent spatial patterns in the growth of *C. dilutus* were evident. Overall, the toxicity data indicate an apparent effect on survival and growth of *C. dilutus* at one of the two near-field littoral areas only (LNF1).

7.4 Benthic Invertebrate Community

Benthic invertebrate community samples from near-field, far-field and far-far-field littoral areas of Quesnel Lake were compared to two reference areas within Quesnel Lake (Table 4.1; Figure 4.4) in a Multiple Control-Impact (MCI) design. Samples were collected by petite ponar grab sampler at five stations per area.

7.4.1 Primary Metrics

Mean benthic organism density (individuals/m^2) of the exposed areas (near-field, far-field and far-far-field) did not differ significantly from both reference areas (Appendix Table G.15; Figure 7.6). However, taxon richness at both near-field areas (LNF-1 and LNF-2) was significantly lower than at both reference areas. A low number of taxa relative to reference can be indicative of a degraded benthic invertebrate community (Pielou 1974; Begon et. al. 1996). Neither Simpson's Diversity nor Simpson's Evenness differed at any of the exposed areas relative to both reference areas.

7.4.2 Community Composition

Dominant invertebrate taxon groups at the Quesnel Lake littoral areas were non-biting midges (Chironomidae), oligochaete worms, and amphipods (Figure 7.7; Appendix Tables G.16-17). Moderate representation (5 to 10% overall) was also indicated by clams and mussels (bivalves), snails (gastropods), leeches (Hirudinae), mites (Acari) and EPT taxa (Ephemeroptera, Plecoptera, Trichoptera; Figure 7.7; Appendix Tables G.16-G.17).

The Bray-Curtis index of dissimilarity (BC index) did not differ at any exposed area relative to both reference areas (Figure 7.8; Appendix Table G.15). However, both near-field areas differed significantly from reference area 1 (the Horsefly Bay reference), suggesting community-level differences relative to this reference that appear to be due to lower proportions of EPT taxa at LNF1 and LNF 2 (Figure 7.8). No other consistent exposure area versus reference area differences in the relative proportions of other taxon groups were observed; however, percent Chironomidae differed significantly between the two reference areas (with higher representation at the North Arm reference [71.5 ± 17.8%] than at the Horsefly Bay reference [11.5 ± 5.7%] and exposed stations that were generally intermediate; Figure 7.8; Appendix Table G.16). Correspondence Analysis axes did not

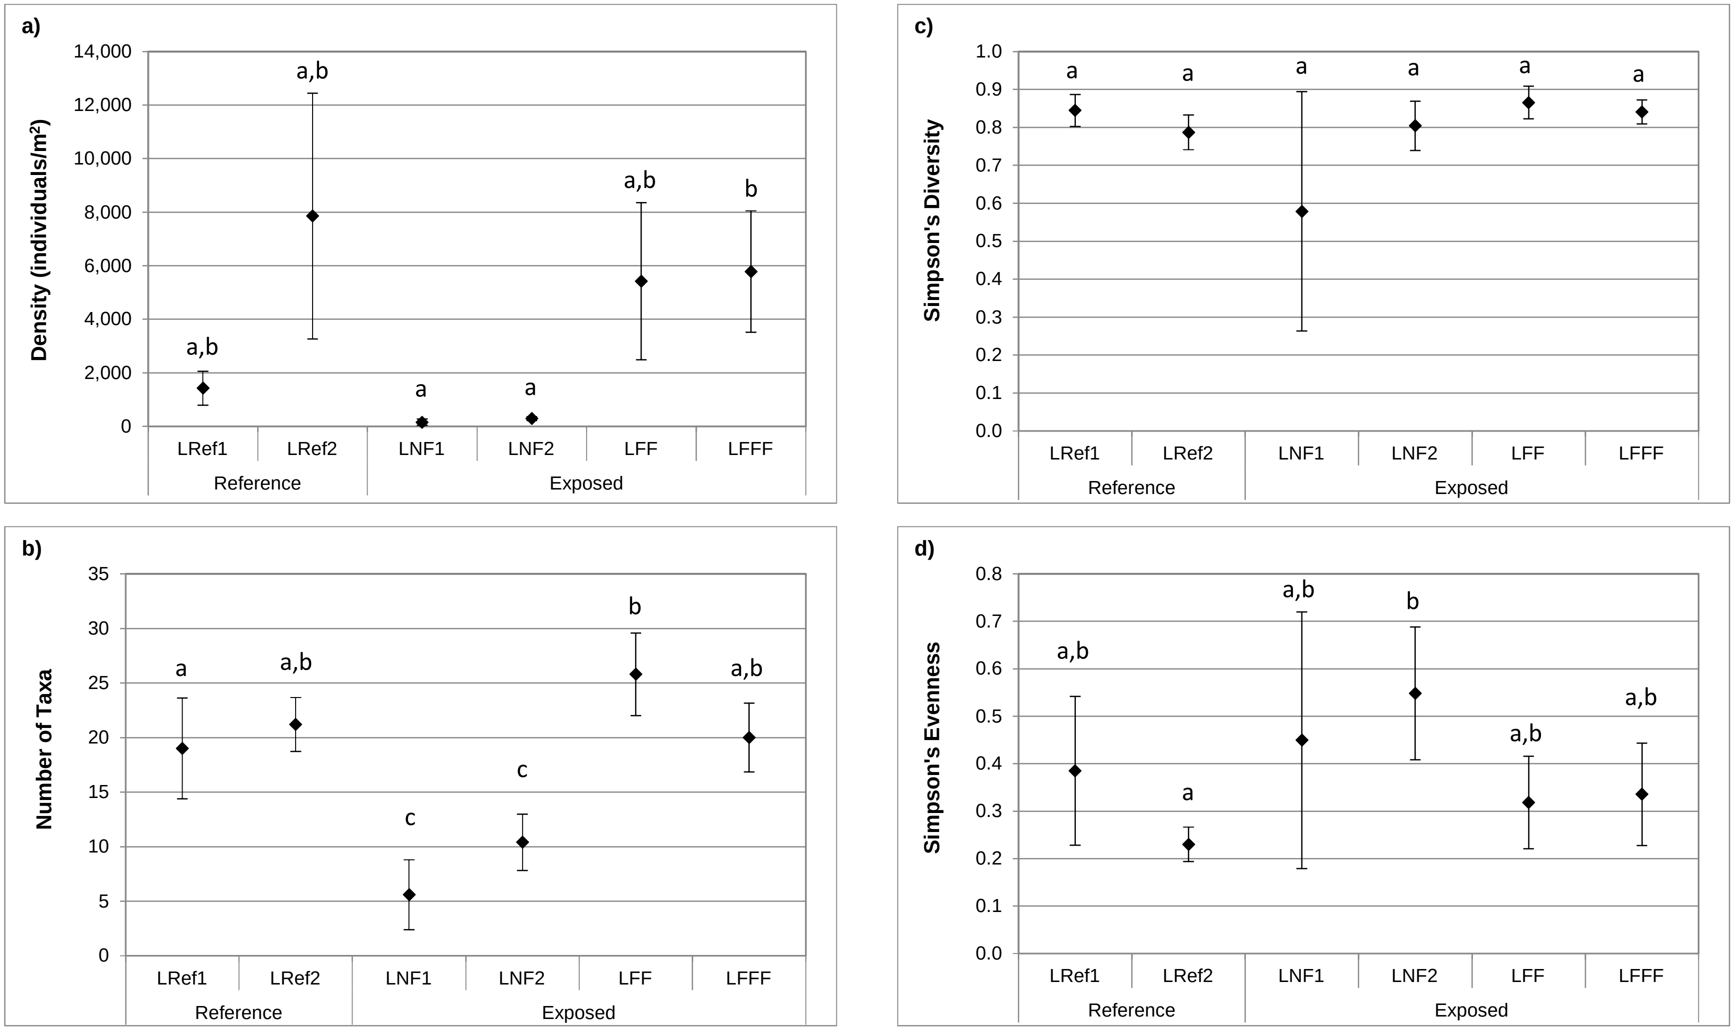

Figure 7.6: Comparison of a) Density, b) Number of Taxa, c) Simpson's Diversity and d) Simpson's Eveness, Mount Polley Mine, 2014 Quesnel littoral area comparisons. Data represents area means and 90% confidence intervals. Different letters above data points indicate areas that were significantly different ($p < 0.1$).

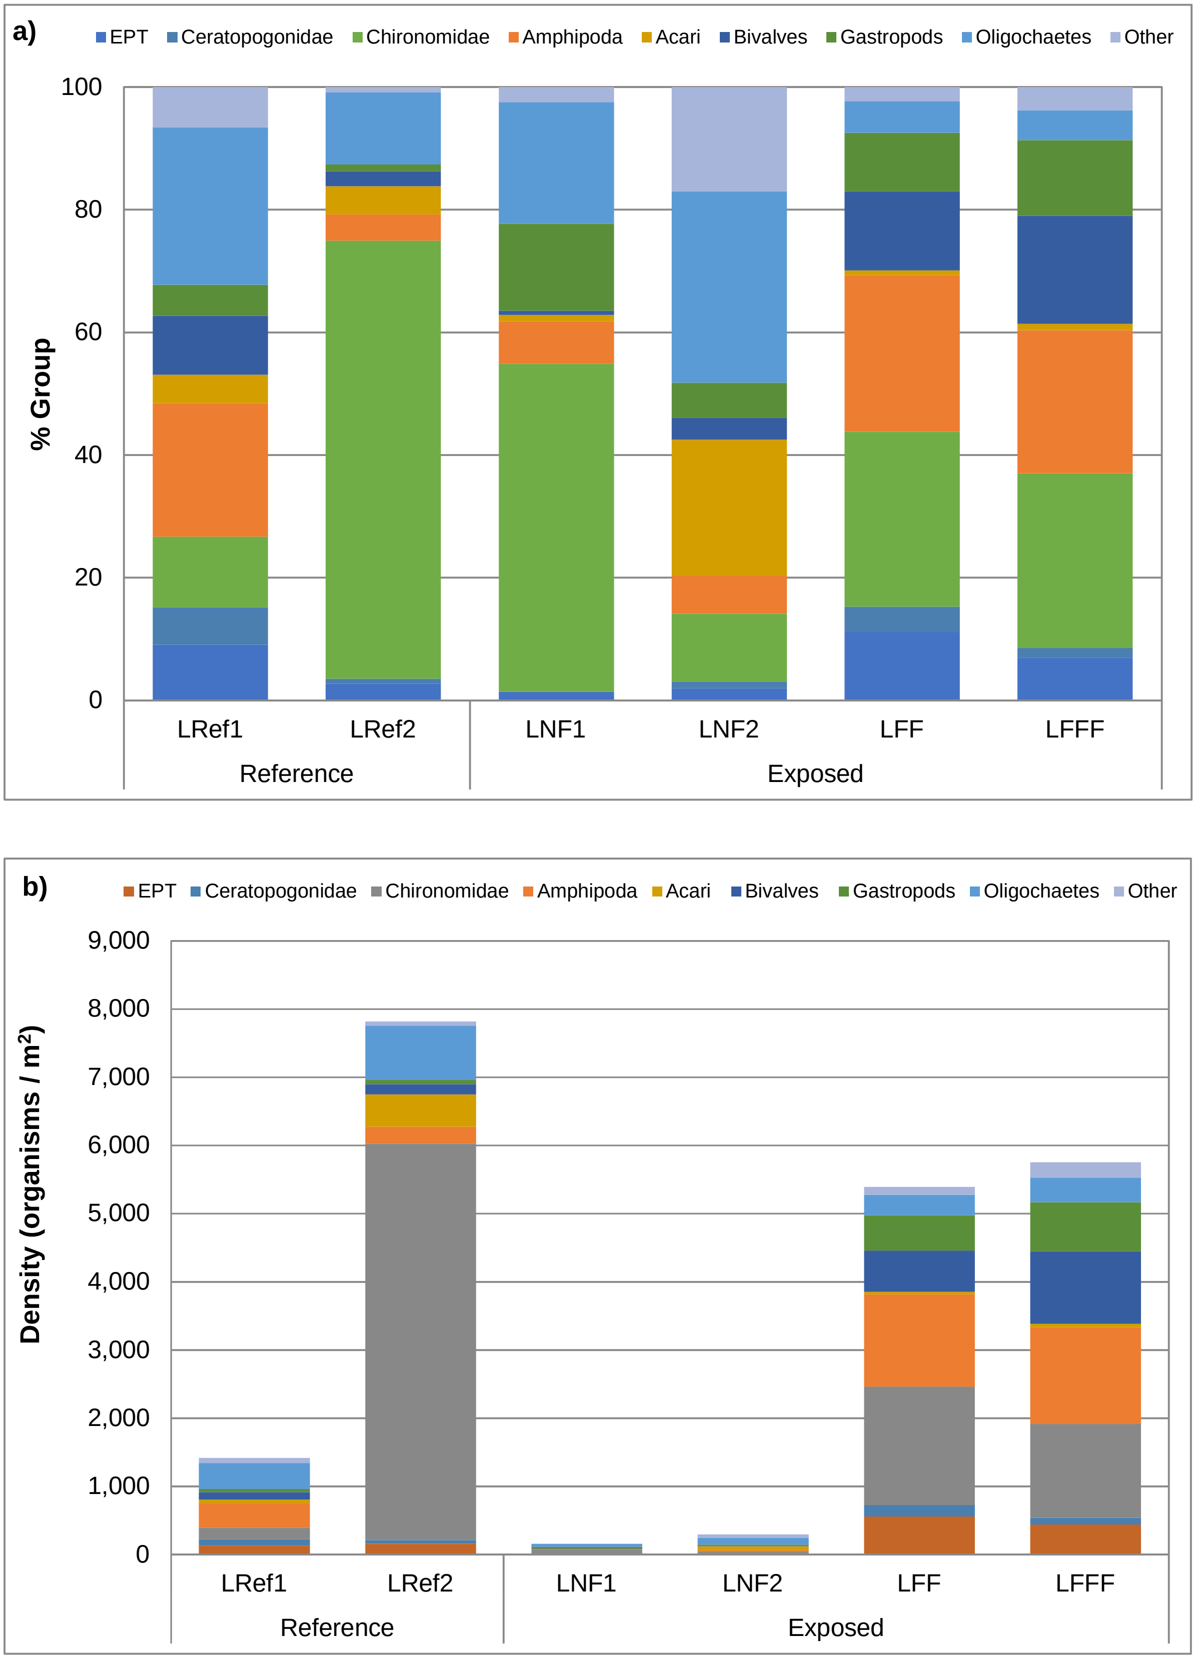

Figure 7.7: Relative mean proportions (a) and mean density (b) of major benthic invertebrate groups within Quesnel Lake littoral sampling areas, Mount Polley Mine, 2014.

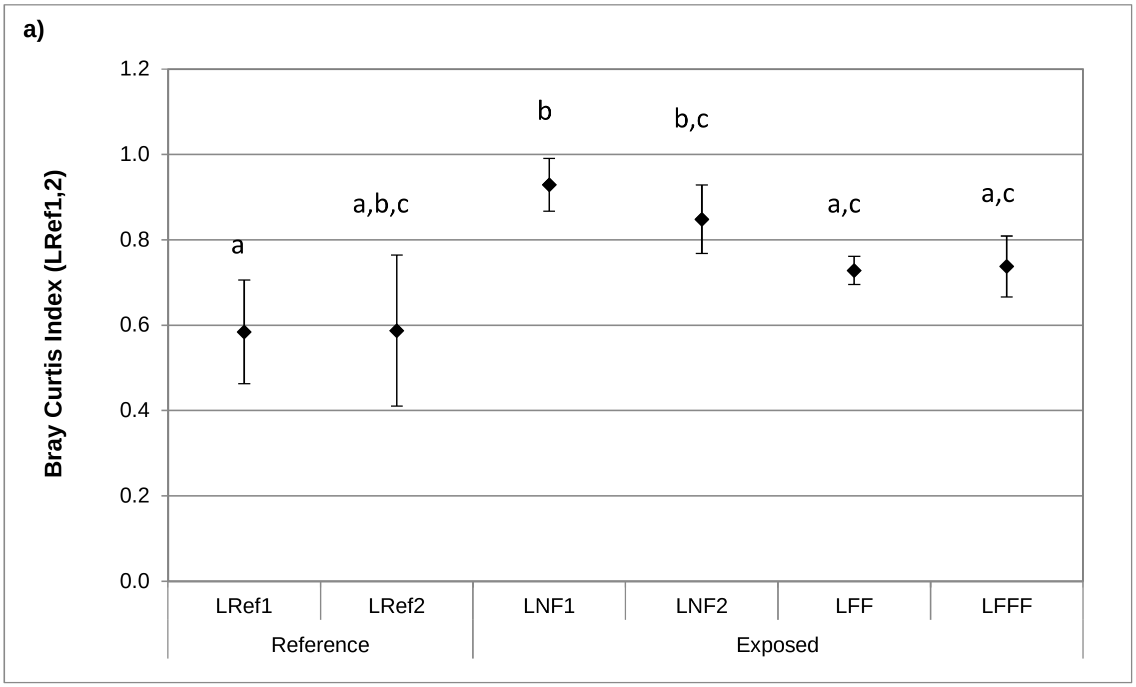

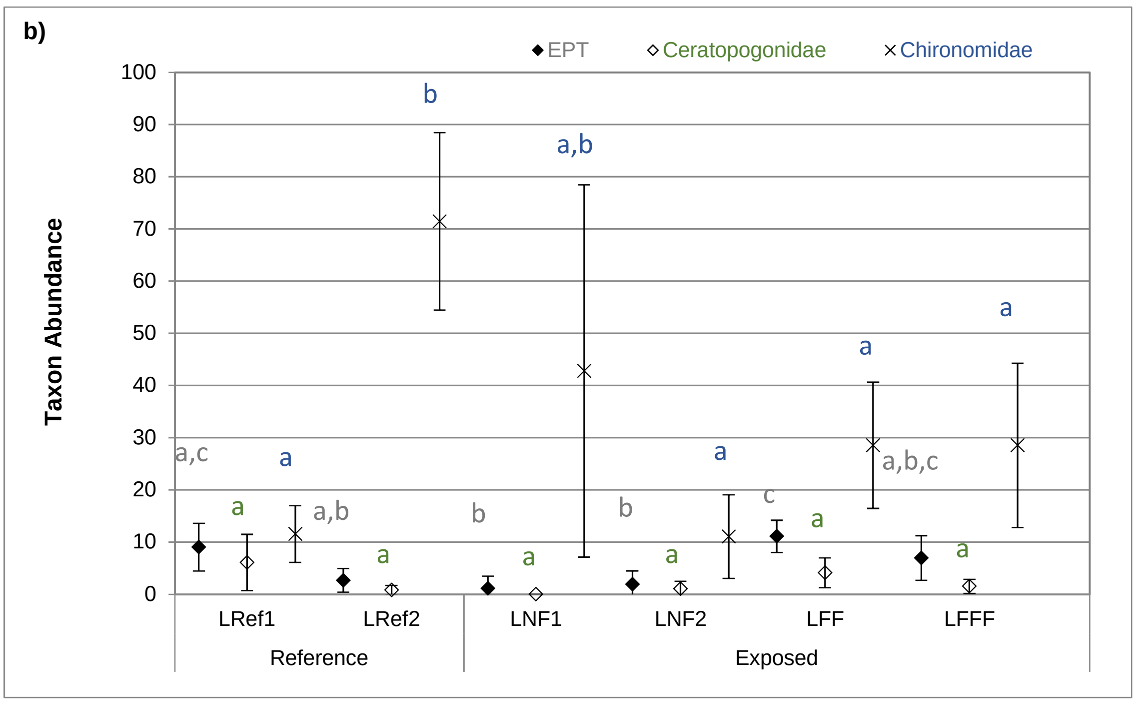

Figure 7.8: Comparison of a) Bray Curtis Index, b) Taxon Abundance (EPT, ceratopogonidae, chironomidae), c) Taxon Abundance (amphipoda, acari, bivalves) and d) CA Score, Mount Polley Mine, 2014. Quesnel littoral area comparisons. Data represents area means and 90% confidence intervals. Different letters above data points indicate areas that were significantly different ($p < 0.1$).

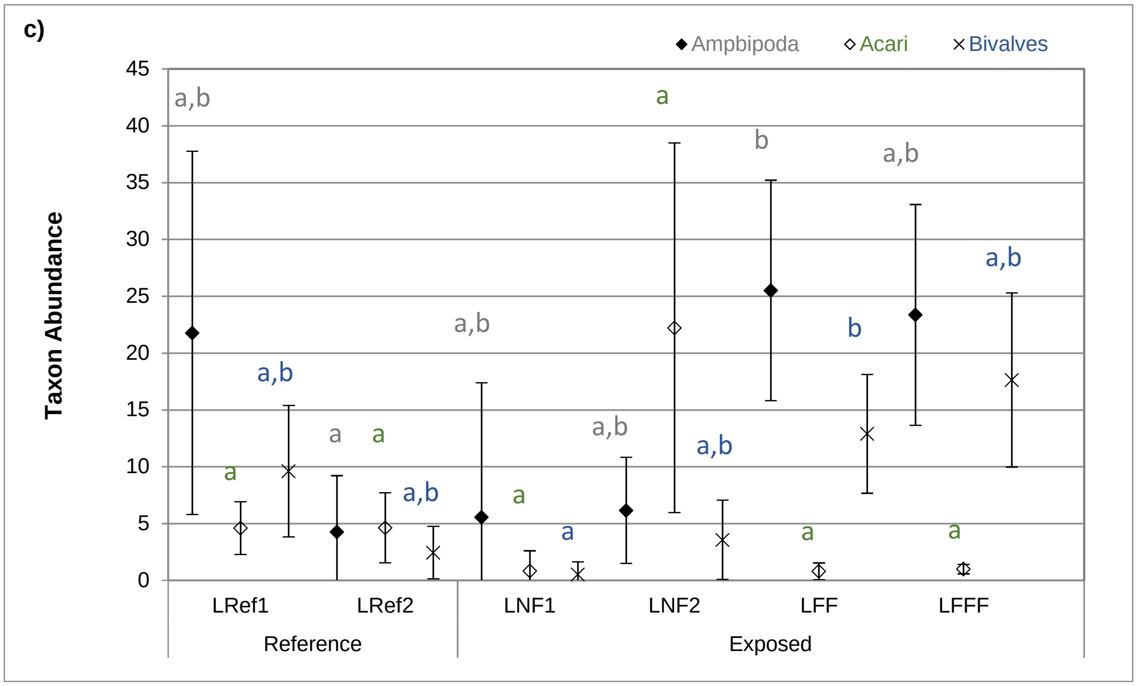

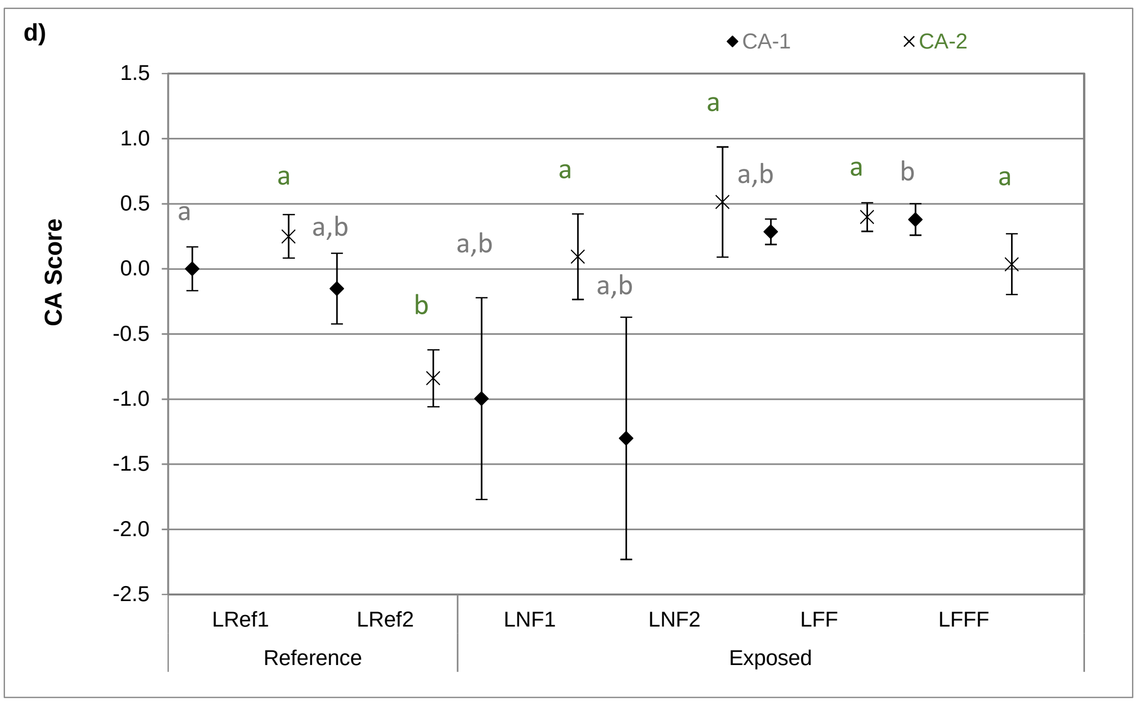

Figure 7.8: Comparison of a) Bray Curtis Index, b) Taxon Abundance (EPT, ceratopogonidae, chironomidae), c) Taxon Abundance (amphipoda, acari, bivalves) and d) CA Score, Mount Polley Mine, 2014. Quesnel littoral area comparisons. Data represents area means and 90% confidence intervals. Different letters above data points indicate areas that were significantly different ($p < 0.1$).

differ significantly at any exposed area relative to both references, supporting the findings of the BC Index (Figure 7.8). However, CA axis 2 (16.3% of community variance) did highlight a difference in community composition at the near-field areas relative to reference area 2. This represents a difference in the benthic community of reference area 2 (the North Arm reference) relative to all other areas that is best described by a greater relative abundance of non-biting and biting midges (Chironomidae and Ceratopoginidae) and fewer mites (Acari) relative to other areas (Figure 7.8; Appendix Figure G.18).

7.5 Correlation Analysis

Correlation analysis was conducted between the biological endpoints (sediment toxicity test endpoints and benthic invertebrate community endpoints) and dissolved oxygen, specific conductance, percent fines, sediment TOC content, sediment concentrations of POIs, IPs, PCA axes and selective copper extracts (Table 7.8). There were few relationships between the toxicity test endpoints and the sediment physical/chemical measures at the Bonferroni-adjusted p-level. Both survival and growth of *H. azteca* were negatively correlated with easily reducible copper, and survival of *C. dilutus* was negatively correlated with sediment PCA Axis 2 and carbonate copper (Table 7.8; Appendix Figure I.7). Sediment PCA-2 primarily represents thallium, nickel and chromium, which are not failure-related, but are higher at reference area 2 (the North Arm reference) and LFFF relative to other areas (Figure 7.2). Additional relationships significant at $p<0.01$ included positive relationships between *H. azteca* survival and growth, and *C. dilutus* survival and TOC content and nickel concentration, as well as several additional negative relationships with IPs and copper extracts (Table 7.8). Although correlation analysis is not necessarily indicative of cause, the negative relationships with carbonate copper, easily reducible copper, and the positive relationships with TOC suggest some impairment in association with plausible effect mechanisms (e.g., smothering, low TOC high POI and IP concentrations).

A substantial number of relationships between benthic invertebrate community metrics and sediment chemistry were observed at the Bonferroni-adjusted p-level (Table 7.8). Bray-Curtis index of dissimilarity was negatively correlated with dissolved oxygen, indicating greater dissimilarity at lower dissolved oxygen concentrations. Benthic invertebrate density was positively correlated with specific conductance and sediment nickel concentration and negatively correlated with molybdenum and sediment PCA Axis 2, as well as copper in the exchangeable, carbonate and easily reducible phases (Table 7.8; Appendix Figure I.7). Number of taxa was negatively correlated with a number of POIs (arsenic, copper and manganese) and IPs (barium, molybdenum, silver, sodium and

Table 7.8: Spearman's Rank Correlation results for correlation of toxicity test results and benthic invertebrate community metrics versus sediment physical characteristics, parameters of interest, indicator parameters, PCA axes scores, copper extracts (all in < 2mm sediment fraction) in Quesnel Lake littoral sampling areas, Mount Polley Mine, 2014 [1,2.]

Significant correlation; p-value < 0.00009 (Bonferroni corrected p-value for 556 comparisons among Table 7.8 and Appendix Table I.3).

Correlation scatterplot inspected; p <0.01.

[1] Values < method detection limit (MDL) were used at the MDL for calculations. Normalized survival and growth are relative to associated laboratory contro

[2] For sampling areas where 5 toxicity field replicates were analysed for each station (Sampling areas LRef1, LNF1, and LNF2), mean survival and growth measures (of the 5 replicates per station) were used for correlations with individual sediment chemistry measures from each static

[3] Copper extract results for sampling areas LRef2, LFF, and LFFF are for a single composite sample. As a result, the single copper value available for each fraction was used in correlations with each of the 5 toxicity replicates from each of these sampling areas.

Note: n=30 for all correlations; except n=19 for correlations with mercury.

NA = Correlation was not performed between these two parameters.

strontium), as well as exchangeable, carbonate and easily reducible copper, and was positively correlated with sediment PCA 1 (which represents low concentrations of POIs and IPs; Figure 7.2). Bray-Curtis index of dissimilarity was positively correlated with a number of POIs (arsenic, copper, iron and manganese) and IPs (calcium, molybdenum, silver, strontium and vanadium), as well as exchangeable and organic copper, and was negatively correlated with sediment PCA 1 (which represents low concentrations of POIs and IPs; Figure 7.2). Although correlation does not necessarily indicate cause, most of these associations suggest adverse effects to density, taxon richness and community structure associated with elevated concentrations of POIs and IPs. This finding is further supported by a number of additional relationships, including positive relationships between percent bivalves and CA axis 1 (representing Hydrozetidae [mites], Empididae [dance flies], Chironomus [non-biting midge] and Orthocladius [non-biting midge] in the positive direction and Probezzia [Ceratopogonidae - biting midge] and Caenis [mayfly] in the negative direction; Appendix Figure I.8) and TOC content, negative relationships between the proportion of sensitive EPT taxa and iron, sodium and easily reducible copper, and negative relationships between the proportion of bivalves and sodium and easily reducible copper (Table 7.8; Appendix Figure I.7). Negative relationships between benthic invertebrate community CA axis 1 and sodium, exchangeable copper, carbonate copper and easily reducible copper (Table 7.8; Appendix Figure I.7) are equivocal due to an absence of clear tolerance differences between the taxa represented by CA axis 1.

7.6 Data Integration, Summary and Spatial Extent

Sediment collected from littoral areas of Quesnel Lake following the dam failure was characterized by increasing TOC with distance from Hazeltine Creek, near-field concentrations of copper and iron greater than SQG PELs and reference concentrations, and near-field concentrations of arsenic and manganese greater than TELs and reference but similar to or lower than pre-event concentrations recorded in Hazeltine Creek. Sediment geochemical evaluations indicated that, for most POIs and IPs, concentrations were mostly in the residual phase, a fraction that is not considered mobile or biologically available. However, copper was a notable exception, with the majority occurring in the "organic" phase (which appears to be mineral), and with concentrations in the exchangeable, carbonate and easily reducible phases at near-field areas greater than reference. Separate integrated consideration of mineralogy, sequential extraction results and mineral solubility indicates that these forms would not be mobile under environmentally realistic conditions (SRK 2015).

Sediment toxicity testing indicated no adverse effects to *H. azteca* and *C. dilutus* at far-field and far-far-field areas, but sediments collected at near-field area 1 caused reduced survival and growth of *C. dilutus* relative to reference and laboratory controls. Benthic invertebrate community assessment indicated that the benthic invertebrate community of the Quesnel Lake littoral near-field areas (near-field area 1 and near-field area 2) had lower taxon richness than both reference areas. Nonetheless, community composition, although variable among areas, was not significantly different at the exposed areas relative to both references.

Correlation analysis indicated negative relationships between survival and growth of *H. azteca* and easily reducible copper and a negative relationship between survival of *C. dilutus* and carbonate copper. Positive relationships to TOC content were apparent for the same endpoints. Correlation analysis also indicated a number of significant relationships between benthic invertebrate community metrics and sediment metal concentrations (including selective copper extracts) that suggest effects to density, taxon richness and community structure associated with elevated concentrations of tailings dam failure-associated POIs and IPs.

Overall, an impact of the dam failure was evident in sediment quality of near-field littoral areas of Quesnel Lake. As in Hazeltine Creek and Polley Lake, copper represents the analyte of greatest concern, both with respect to its absolute concentration relative to guidelines and its geochemical partitioning. Sediment toxicity testing indicated that toxicity was restricted to the near-field areas, which were also the areas of lowest TOC content and highest POI concentrations. Benthic invertebrate communities at the near-field areas had fewer taxa than both reference areas, and significant negative relationships between density, taxon richness, community composition and specific conductance and sediment metal concentrations (including selective copper extracts) suggest a failure-related effect at near-field areas. As the positive influence of TOC cannot be separated from potential negative effects due to elevated metal concentration (including copper in potentially available forms), it is uncertain whether the effects were associated with moderately lower dissolved oxygen physical (i.e., due to smothering or low TOC) or chemical, but they are nonetheless related to the tailings dam failure. Both physical observations and concentrations of POIs and IPs indicate that the spatial extent of the tailings dam failure on Quesnel Lake littoral sediment quality is restricted to near-field areas.

8.0 QUESNEL LAKE - PROFUNDAL

Sediment quality impact characterization of the profundal zone of Quesnel Lake included sediment chemistry, sediment geochemical characterization, sediment stratigraphy, toxicity testing, and benthic invertebrate community characterization (Table 4.1; Figure 4.5). Data Quality Assessment (DQA; Appendix C with supporting data in Appendix J) indicated that sediment quality data, toxicity test results and benthic invertebrate community data were of good quality and can therefore be used in the sediment quality impact characterization.

8.1 Sediment Physical and Chemical Characterization

Surficial sediment (top 5 cm) collected in the near-field and far-field profundal areas of Quesnel Lake (PNF, PFF1 [downstream; north of the Hazeltine Creek mouth], PFF2 [upstream; south of the Hazeltine Creek mouth]; Figure 4.5) was generally composed entirely of light grey or tan coloured fines that varied in consistency from fairly liquid to more consolidated. Within the far-far-field sampling area (PFFF), sediment was generally composed of a thin layer of light grey or tan-coloured fines over distinctly stratified brown silt and dark grey clay-like fines separated by a rust-coloured layer. Sediment collected in both reference areas was similar to one another, with brown or rust coloured silt present at the surface, and dark grey clay-like fines deeper in the sediment, with these layers generally separated by distinct striations.

Sediment at the four exposed areas and two reference areas in the profundal zone of Quesnel Lake were predominantly silt and clay (Table 8.1; Appendix Table E.54). Sediment at one of the reference areas, area PRef1 located in Horsefly Bay (Figure 4.5), had a higher proportion of sand than all other areas, but was still 67% silt, on average (Table 8.1). Total organic carbon ranged from a low of 0.17% at PNF (directly off the mouth of Hazeltine Creek) to 3.06% at PFFF (the far-far-field area located just south of Cedar Point; Figure 4.5). As also observed in littoral sediments of Quesnel Lake, a spatial pattern of increasing TOC (in this case from concentrations well below reference to concentrations similar to reference) was evident proceeding from the near-field area to the far-far-field area (Tables 8.1 and 8.2), associated with the input of failure-derived materials low in TOC content.

Copper was the only analyte with concentrations in Quesnel Lake profundal near-field and far-field sediment greater than guidelines (PELs) and reference concentrations (Tables 8.1 and 8.2; Figure 8.1). At the far-far-field area, copper concentrations were lower than PEL, but were greater than TEL and remained higher than reference. A number of

Value is > TEL. Values shown in bold text also exceed both Reference 95th Percentile values.

Value is > PEL. Values shown in bold text also exceed both Reference 95th Percentile values.

[1] Data < method detection limit (< MDL) were used at the MDL for the calculation of summary statistics. Means are reported as < MDL if all the data used in their calculation were < MDL.

[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b); TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.

[3] Reference 95th percentile was calculated using displayed data for the <63µm sediment fraction. The 5th percentile is reported for pH.

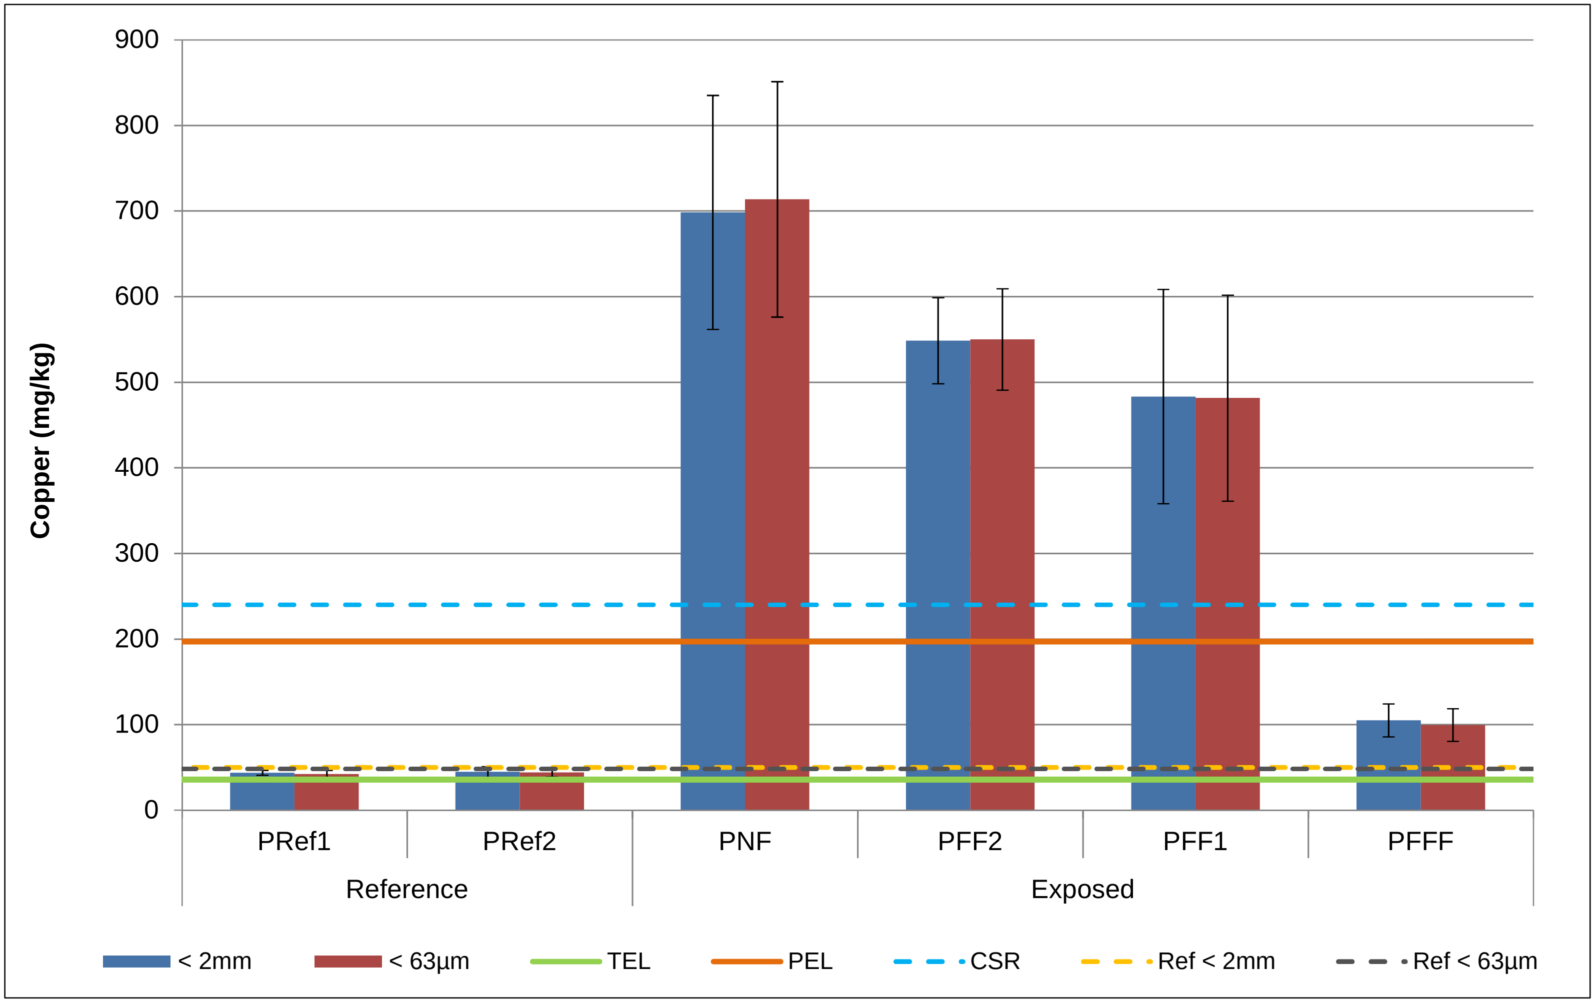

Figure 8.1: Mean copper concentrations (± t*SE) in sediment from profundal sampling areas in Quesnel Lake, Mount Polley Mine, 2014.

TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level; CSR =Contaminated Sites Regulation-Typical.
Ref < 2mm and Ref < 63 µm values are the highest 95th percentile values for each sediment fraction reported among the reference areas (PRef1 and PRef2).

additional analytes were present at the far-far-field area at concentrations greater than guidelines and reference concentrations (arsenic and manganese were greater than PELs; cadmium, chromium and nickel were greater than TEL; Tables 8.1 and 8.2), but were below reference at the near-field and far-field areas (Tables 8.1 and 8.2) and are therefore not considered to be associated with the tailings dam failure. It is notable, however, that concentrations of iron and manganese, although also elevated at one reference area (PRef 2, located at the Quesnel Lake North Arm), were both greater than SQG PELs at the far-far-field area (Tables 8.1 and 8.2). Concentrations of five additional analytes were present in Quesnel Lake profundal sediment at concentrations more than twice reference concentrations (calcium, sodium, strontium, tin and vanadium in near-field and far-field areas only; Tables 8.3 and 8.4). All of these analytes were identified as IPs based on the Hazeltine Creek, Polley Lake and/or Quesnel Lake littoral datasets. In accordance with the framework set out in Section 4.0, copper is designated as a POI and calcium, sodium, strontium and tin are designated as IPs. However, all POIs identified in the evaluations of Hazeltine Creek, Polley Lake and the Quesnel Lake littoral zone (i.e., arsenic, copper, iron, manganese and nickel; Sections 5 to 7) are also considered as part of this characterization of Quesnel Lake profundal sediment in order to track their spatial distribution.

Principal Components Analysis (PCA) distinguished sediments of the near-field exposed area and the far-field area from reference on the basis of axis 2 scores, (indicating higher clay content) and sediments of the far-far-field area from most other areas on a combination of axis 1 and 2 scores indicating greater clay and TOC content (Figure 8.2). PCA was effective in distinguishing sediments of the near-field exposed area and the far-field exposed areas from reference on the basis axis 2 scores, which, with the exception of tin, included all POIs and IPs identified above, thereby confirming their importance in explaining spatial variability. PCA was also effective in distinguishing sediments of the far-far-field area from reference and the near-field and far-field areas on the basis axis 1 scores (indicating higher concentrations of aluminum, arsenic, bismuth, cadmium, chromium, cobalt, iron, lead, manganese, nickel, potassium, thallium, uranium, zinc). Of these, cadmium, chromium and nickel were identified as occurring at concentrations greater than TELs at the far-far-field area only.

Of the POIs and IPs, copper was the most substantially elevated, with mean concentrations up to approximately 3.5 times the PEL and 16 times reference (Tables 8.1 to 8.4; Figures 8.1 to 8.4). Copper concentration was greatest at the near-field area (PNF; Figure 8.1). Unlike copper in Hazeltine Creek and Quesnel Lake littoral sediments, there

[1] The highest mean concentration for each analyte from among the littoral reference areas (PRef1 and PRef2) was used as the reference mean for calculation of the ratio.

[2] Mean values < method detection limit (MDL) were used at the MDL for calculation of exposed to reference ratios.

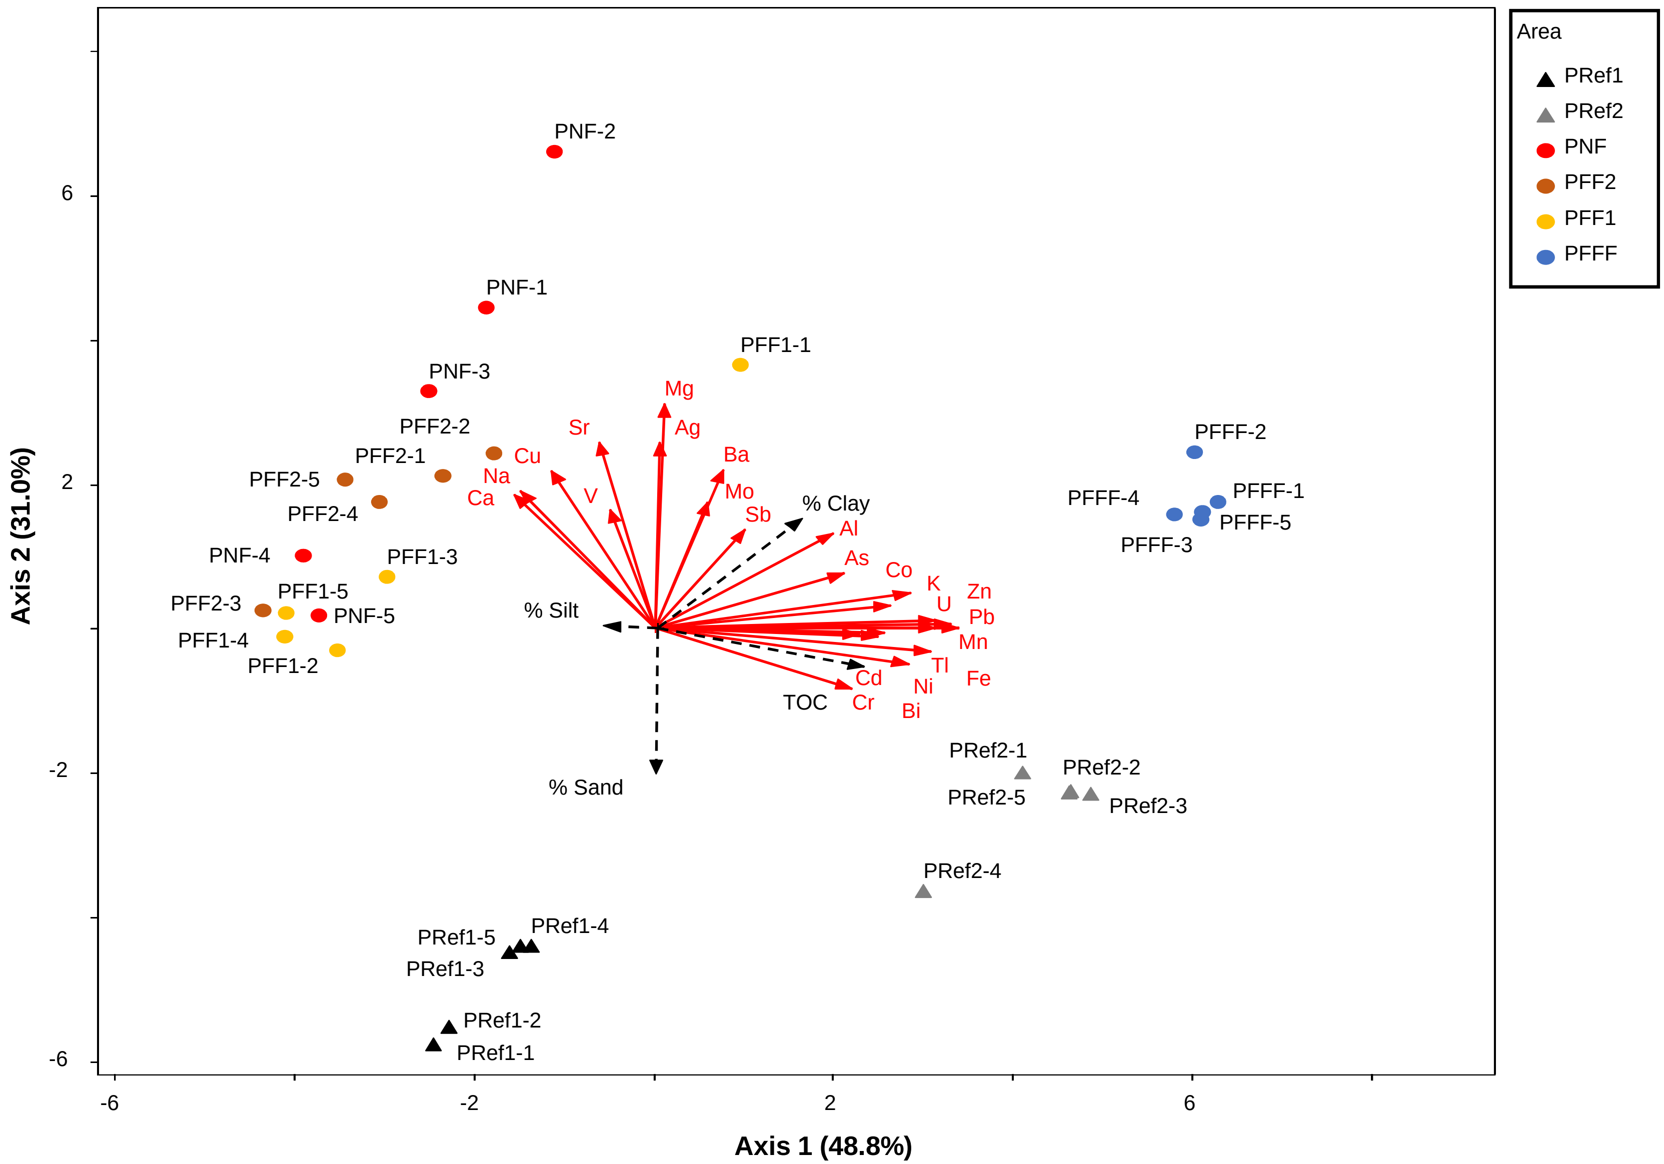

Figure 8.2: **Biplot of principal component analysis (PCA) of metal concentrations in sediment (<2 mm fraction) from Quesnel Lake profundal sampling stations, Mount Polley Mine, 2014. Vector length is proportional to the magnitude of direct correlation of metals (solid red vector lines) and indirect correlation of sediment physical characteristics (black dashed vector lines) with PCA values of each axis (Appendix Tables E.56-E.57). Only metals with significant (p-value <0.010) Spearman's correlation and r-values > 0.7 with either axis are displayed, all sediment physical characteristics are displayed [a].**

[a] Mercury was omitted from calculations due to an incomplete data set.

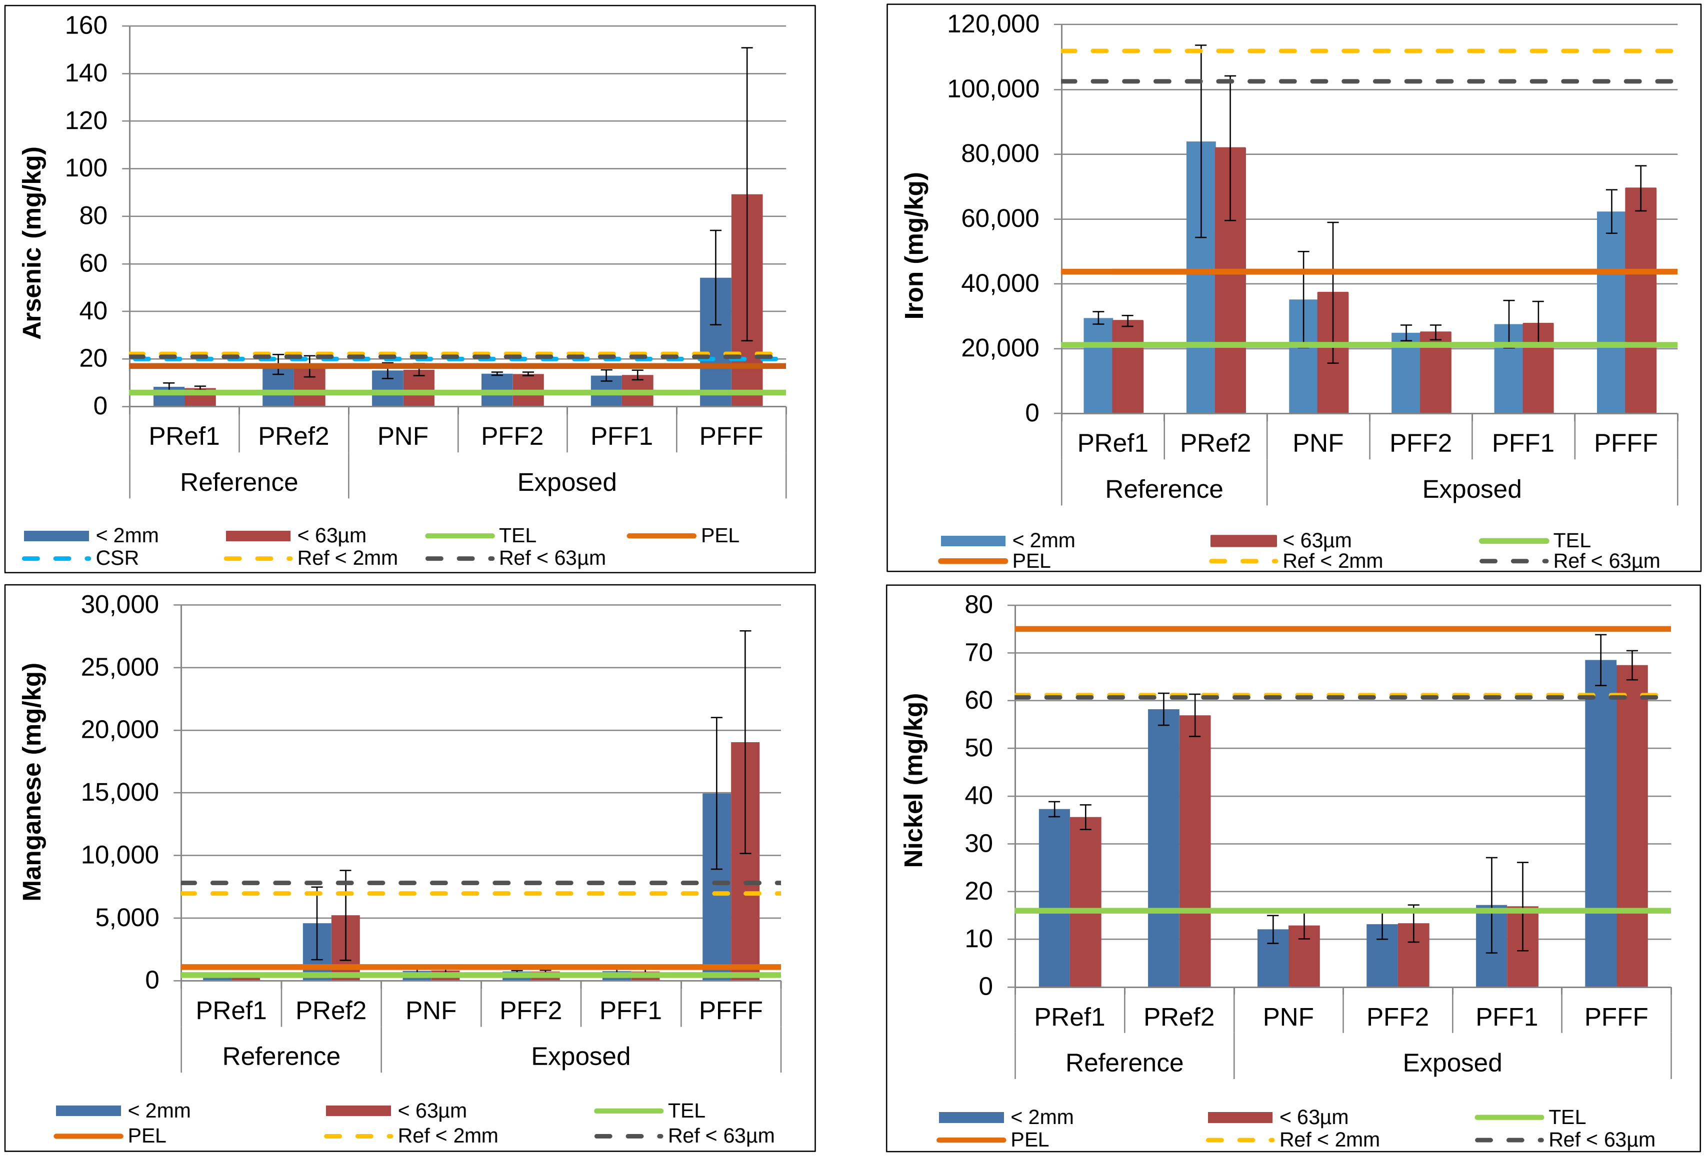

Figure 8.3: Mean metal concentrations (± t*SE) in Quesnel profundal sediment for parameters of interest identified in other sampling areas (Hazeltine Creek, Polley Lake, and Quesnel Lake littoral), Mount Polley Mine, 2014.

TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level; CSR =Contaminated Sites Regulation-Typical.

Ref < 2mm and Ref < 63 µm values are the highest 95th percentile values for each sediment fraction reported among the reference areas (PRef1 and PRef2).

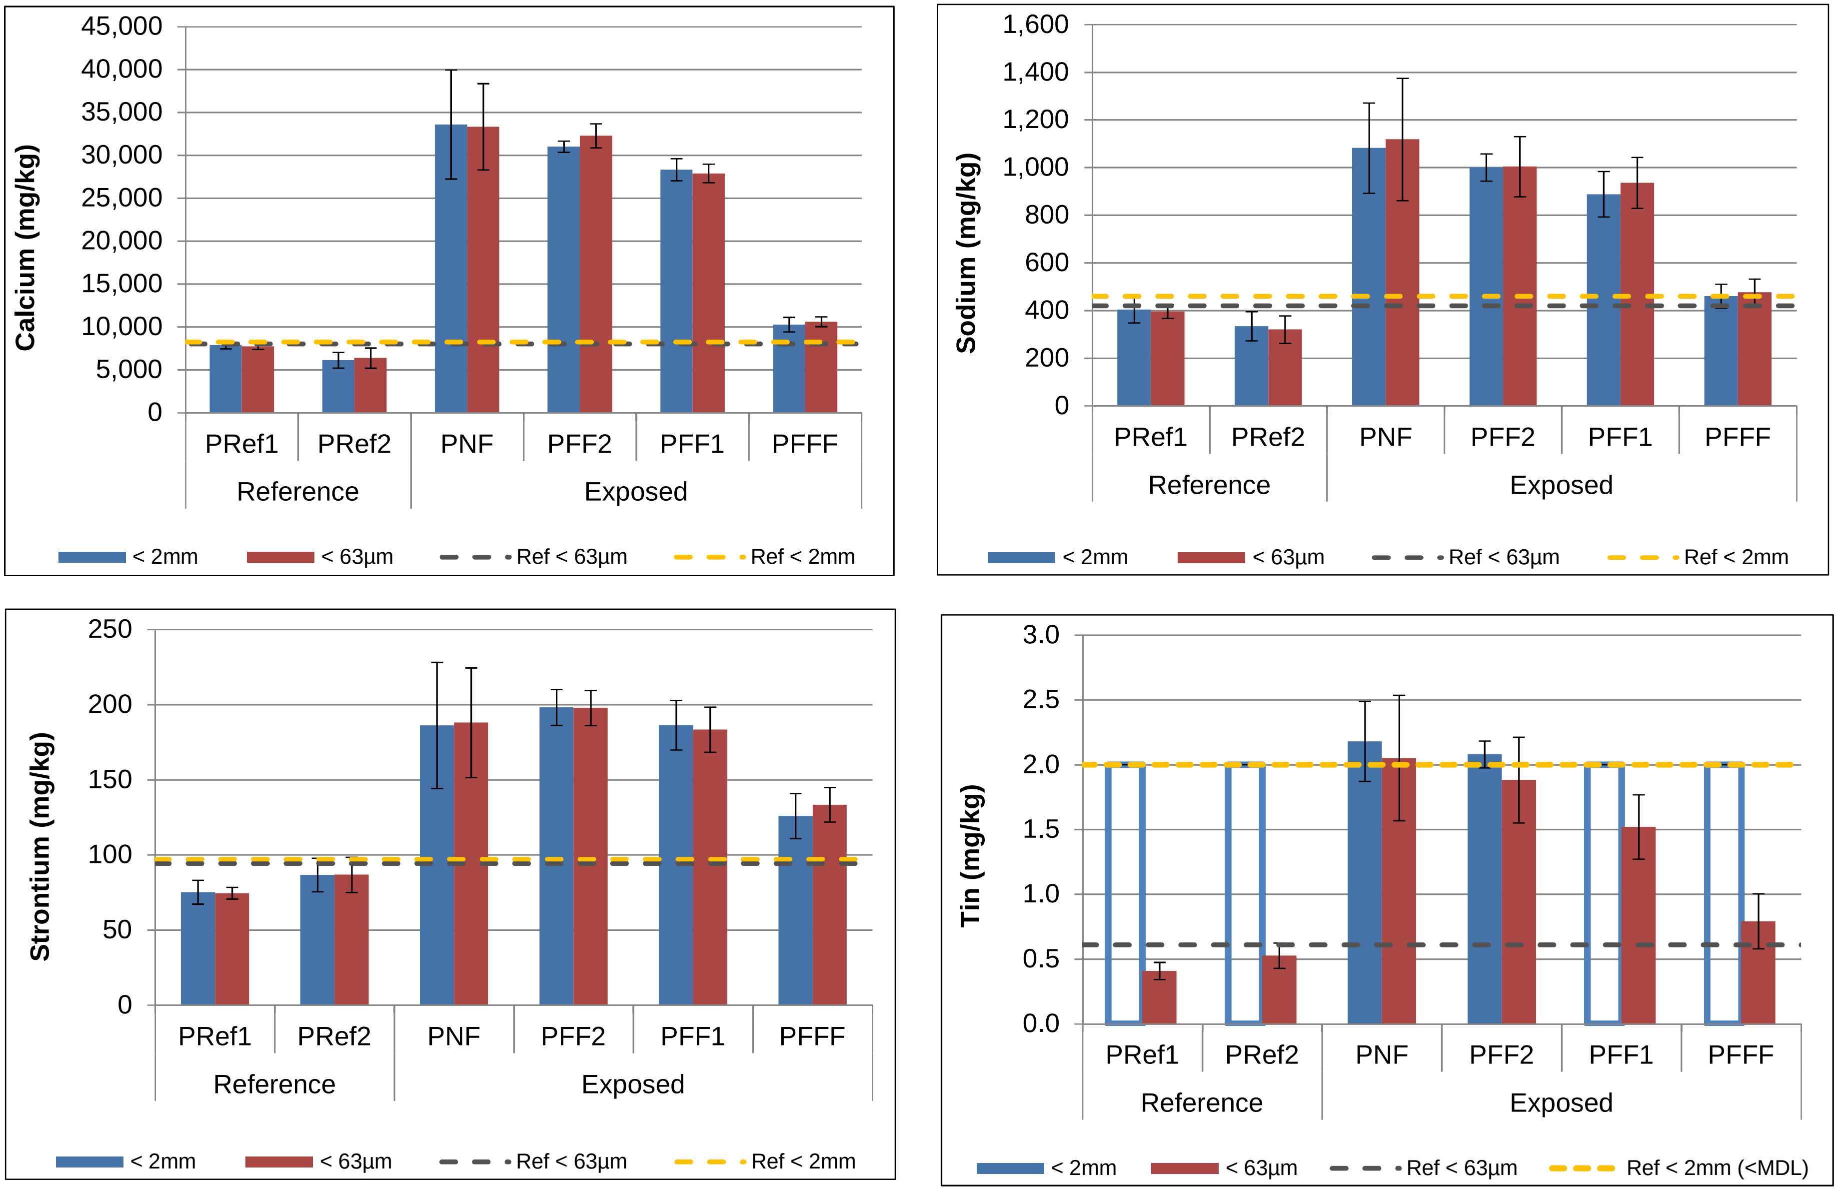

Figure 8.4: Mean metal concentrations (± t*SE) of indicator parameters in sediment from profundal sampling areas in Quesnel Lake, Mount Polley, 2014. Hollow bars indicate all values used to calculate the mean were < the method detection limit (MDL).

Ref < 2mm and Ref < 63 µm values are the highest 95th percentile values for each sediment fraction reported among the reference areas (PRef1 and PRef2).

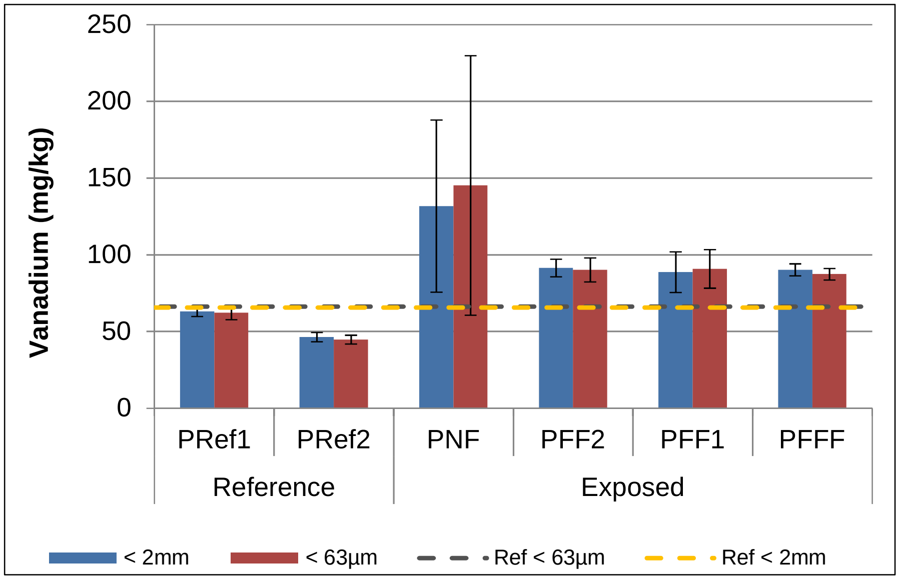

Figure 8.4: Mean metal concentrations (± t*SE) of indicator parameters in sediment from profundal sampling areas in Quesnel Lake, Mount Polley, 2014. Hollow bars indicate all values used to calculate the mean were < the method detection limit (MDL).

Ref < 2mm and Ref < 63 µm values are the highest 95th percentile values for each sediment fraction reported among the reference areas (PRef1 and PRef2).

was no clear enrichment in the <2 mm fraction relative to <63 µm fraction, presumably due to high proportion of silt and clay (≥93%; Table 8.1). Copper concentrations decreased in a step-wise manner with distance from PNF to PFFF and were lower than PEL at PFFF (Figure 8.1). Concentrations of arsenic, iron and manganese decreased with distance from PNF to PFF, but were highest at PFFF, whereas concentrations of nickel increased with distance from PNF (Figure 8.3). Similar to copper, concentrations of all IPs decreased with distance from PNF to PFFF, and with the exception of strontium, were generally similar to reference at area PFFF (Figure 8.4).

Concentrations of copper, calcium, sodium and strontium were all positively correlated with percent fines (percent silt and clay) and negatively correlated with sediment total organic carbon (TOC) content (Table 8.5; Appendix Figure E.30). This is driven by the combination of higher fines, low TOC and high concentrations of copper and IPs at the near-field and far-field areas (Appendix Figure E.30). Concentrations of iron and nickel were positively correlated with sediment TOC content, primarily driven by high concentrations of TOC and these metals at the far-far-field area and reference area 2 (Table 8.5; Appendix Figure E.30).

8.2 Sediment Geochemical Characterization

As previously indicated, there are numerous factors that affect the bioavailability of metals in sediments. While metal concentrations that are below the sediment quality guidelines generally provide a reliable indicator of an absence of effect, sediment quality results that exceed those benchmarks provide a less reliable indication that effects are probable. Geochemical characterization can assist in characterizing the potential mobility and bioavailability of metals associated with mine-influenced sediments.

Selective extractions indicated that concentrations of most POIs and IPs were primarily in the residual phase; that is, they could only be extracted by the strongest acid digest (a combination of concentrated nitric and hydrochloric acid; Table 8.6; Appendix Table E.60; Figure 8.5; Appendix Figures E.31-E.32). As previously discussed, residual metals are unlikely to be mobilized under any conditions that could realistically occur in the environment, nor in interactions with aquatic organisms (i.e., contact with the gill or ingestion) and are therefore considered not biologically available (e.g., Tessier et al. 1979; Campbell and Tessier 1996). Exceptions were observed with copper and manganese. As also observed in Hazeltine Creek, Polley Lake and Quesnel Lake littoral sediments, greatest concentrations of copper at the near-field areas occurred in the “organic” phase (Figure 8.5). As previously discussed (Section 5.2), it is likely that the “organic” phase represents mineral copper. This copper partitioning differed from that observed in

Table 8.5: Spearman's Rank Correlation results for correlation of concentrations of parameters of interest and indicator parameters (in < 2mm sediment fraction) relative to % fines (silt and clay) and total organic carbon in sediment from Quesnel Lake profundal sampling areas, Mount Polley Mine, 2014 [1].

(blue) Value is > TEL. Values shown in bold text also exceed both Reference 95th Percentile values.

(orange) Value is > PEL. Values shown in bold text also exceed both Reference 95th Percentile values.

[1] Data < method detection limit (< MDL) were used at the MDL for the calculation of summary statistics. Means are reported as < the highest displayed MDL if all the data used in their calculation were < MDL. Summary statistics were only calculated for sampling areas with replicate samples (PRef1, PNF,and PFF1) but not for single composite samples (PRef2, PFF2, and PFFF).

[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b); TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.

[3] Displayed reference values are the 95th percentiles of data from reference area PRef1 and are the single values available for reference area PRef2.

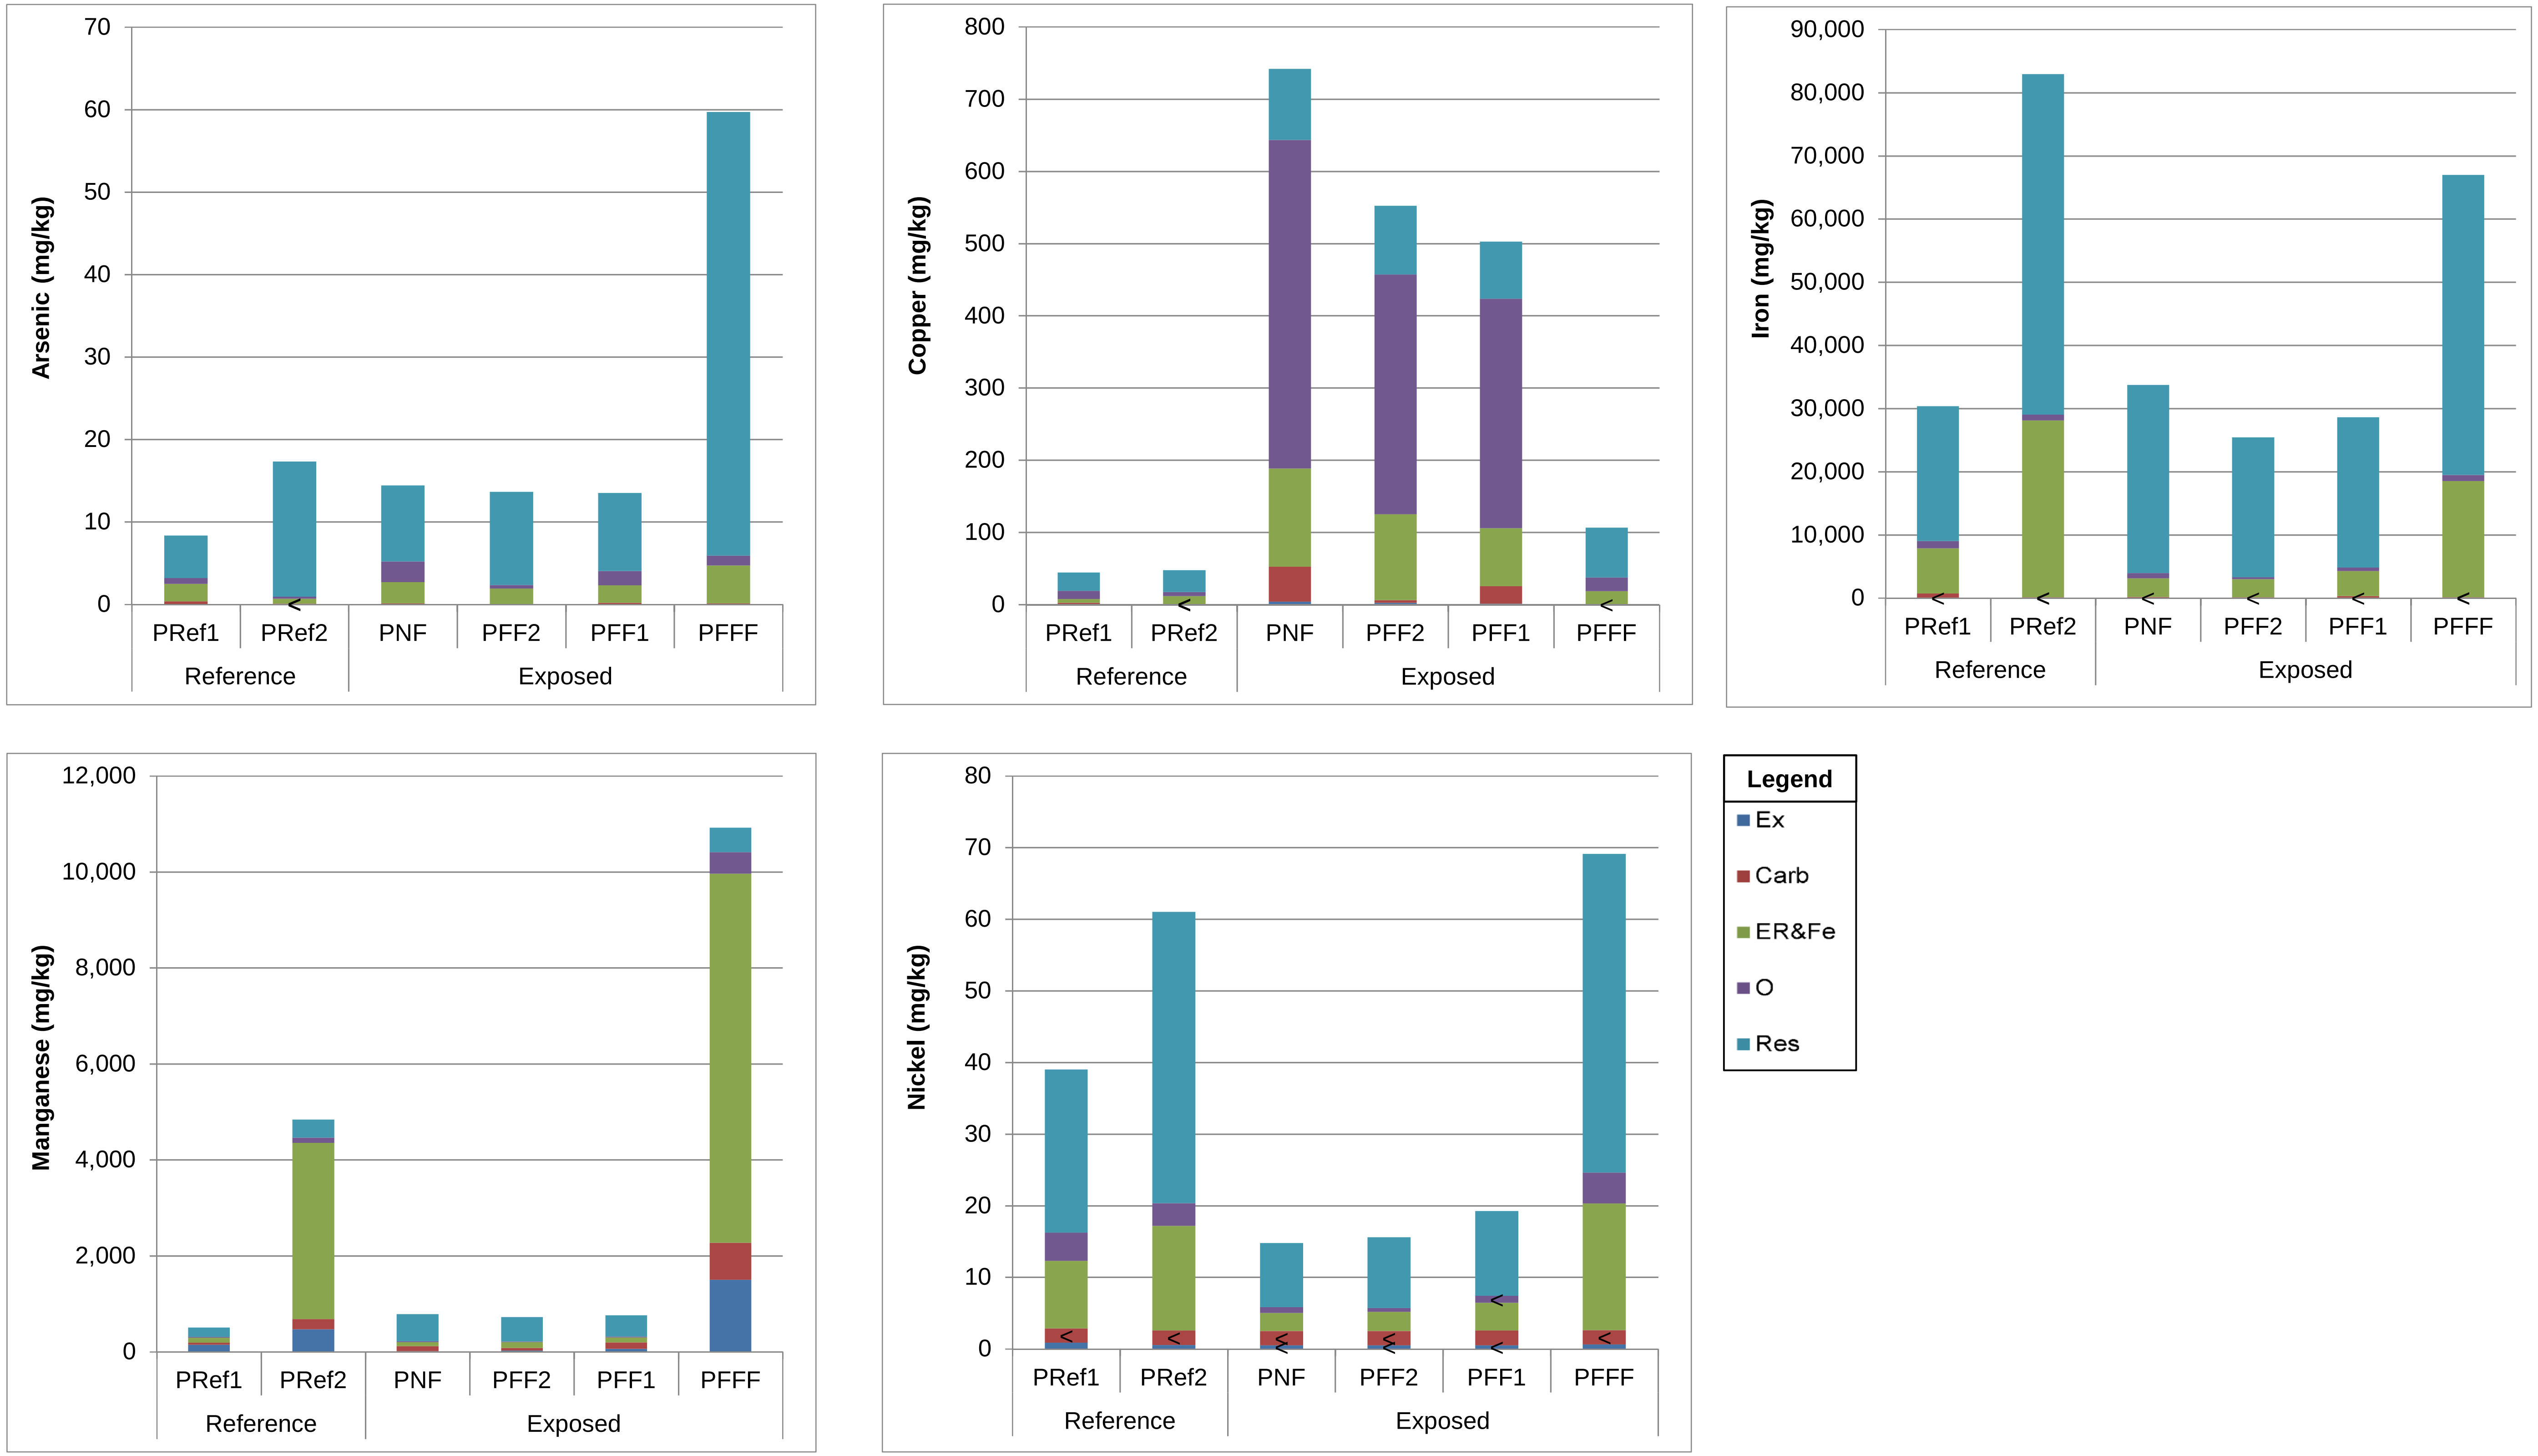

Figure 8.5: Mean concentrations of selectively extracted parameters of interest in sediment from the profundal sampling areas of Quesnel Lake, Mount Polley Mine, 2014. Selective extractions included Exchangeable & Adsorbed Metals (Ex), Carbonate Metals (Carb), Easily Reducible Metals and Iron Oxides (ER&Fe), Organic Bound Metals (O), and Residual Metals (Res).

Values < MDL are indicated with a < symbol. Mean values are plotted for areas with replicate samples (PRef1, PNF, PFF1), single values are plotted for composite samples (PRef2, PFF2, PFFF).

reference sediment (and far-field sediment), where more than approximately 60% of sediment-associated copper was in residual form (Figure 8.5; Appendix Figure E.31). Greatest concentrations of manganese at the near-field and far-field areas were in the residual phase, but at the reference and far-far-field areas, were in the easily reducible phase, possibly representing surface enriched, redox sensitive manganese oxides.

Concentrations of copper in Fractions 1 to 3 (exchangeable + carbonate bound + reducible) at near-field and far-field areas exceeded reference (Figure 8.5; Appendix Table E.60; Appendix Figure E.31). However, separate integrated consideration of mineralogy, sequential extraction results and mineral solubility indicates that these forms would not be mobile under environmentally realistic conditions (SRK 2015). Therefore, sediment copper also appears to be present in Polley Lake sediments in forms that are not mobile and this immobility suggests limited concern for aquatic biota.

Shake flask tests indicated low mobility of metals associated with Quesnel Lake profundal sediments, with copper being the only metal mobilized in shake flask tests of near-field and far-field exposed area sediment to concentrations greater than British Columbia Water Quality Guidelines (BCWQGs) and reference (Table 8.7; Appendix Table E.61). Concentrations of manganese mobilized from reference area sediments also exceeded BQWQGs and were higher still at area PFFF, although the spatial pattern in concentrations (i.e., higher concentrations at PFFF than PNF or PFF) suggest that the latter was not failure-related (Table 8.7; Appendix Table E.61). As previously stated, BCWQG do not apply to sediment leachates, but are used herein as an indication of low mobility.

Acid-Base accounting results indicated that the potential for acid generation generally increased with distance from the influence of the dam failure (Appendix Table E.12 and E.62). Neutralization potential ratio (NPR; the ratio of neutralization potential to maximum potential acidity) was 8.2 to 13 at the near-field and far-field areas and decreased to 6.4 at the far-far-field area (Appendix Table E.12). NPR greater than 4 indicates no potential for Acid Rock Drainage (ARD; Price 1997). Decreasing NPR with distance from Hazeltine Creek indicates that acid potential associated with the impacted sediments is lower than reference and far-field sediments. Lowest NPR (3.9) was observed in the reference area PRef1 located in Horsefly Bay (Appendix Table E.12).

8.3 Sediment Stratigraphy

Sediment cores for characterization of vertical stratigraphy (examination of physical and chemical changes with depth below surface) were collected from the near-field profundal

Table 8.7: Summary of leachable (Shakeflask) metals data for sediment from Quesnel Lake profundal sampling areas, Mount Polley Mine, 2014. Data are based on bulk sediment [1]. Only analytes with detectable concentrations are displayed.

[3] Hazardous Waste Regulation (Government of British Columbia 1988)

[4] Displayed reference values are the 95th percentiles of data from reference area PRef1, and are the single values available for reference area PRef2.

area in Quesnel Lake (Figure 4.5) at a station depth of 108 m. Two cores were collected; one for sediment chemistry profiling and one for pore-water chemistry profiling.

8.3.1 Sediment Core Observations

The two near-field cores were similar and showed little to no observable horizons. The top 0.5 to 1 cm of both cores was beige in colour, and the remaining core was a darker grey-brown (Appendix Figure E.33). During sediment core sectioning, no further changes in sediment characteristics were observed, but it was apparent that the sediment had high porosity such that the entire length of both sediment cores (up to 72 cm) was unconsolidated, and consisted almost entirely of event-derived material.

The lack of horizons (differences in colour and/or texture with distance from surface) in the sediment cores was consistent with the nature of the deposition (i.e., the sediment was not deposited in a seasonal or chronological nature, but more through physical settling with the larger, more dense particles settling out first). Since the smaller particles were still settling at the time of collection, there would also have been insufficient time to establish post-depositional geochemical processes (early diagenesis) which lead to concentration profile structure in sediment core horizons.

8.3.2 Sediment Chemistry Profiles

The chemistry of the top 12 cm of sediment (in 1 cm increments) was screened against BC SQGs. Copper and manganese concentrations were higher than the PEL throughout the sediment core. Although manganese was higher than the PEL (but lower than in surficial reference sediment of the Quesnel Lake North Arm; Tables 8.1 and 8.2), it was at the same order of magnitude as the PEL, while copper was approximately ten times the PEL throughout the core. Arsenic, iron, and nickel concentrations were higher than the TEL throughout the core, while zinc concentrations in sediment only exceeded the TEL in the top 1 cm of the core (Figure 8.6). A number of these analytes were identified as greater than TEL or PEL at reference areas (arsenic, copper, iron, manganese and nickel; Tables 8.1 and 8.2) and therefore the noted elevations were not entirely failure-related.

The sediment chemistry profiles for aluminum, arsenic, copper, iron, lead, manganese, nickel and zinc showed little variation in concentration with depth (Figure 8.6). This was consistent with the nature of deposition of failure-related material (i.e., with no chronological patterns or diagenesis occurring). Sediment chemistry depth profiles of metals with relatively high concentrations (aluminum, copper, iron, manganese, and to some extent zinc) showed slightly higher concentrations in surficial sediment (the top

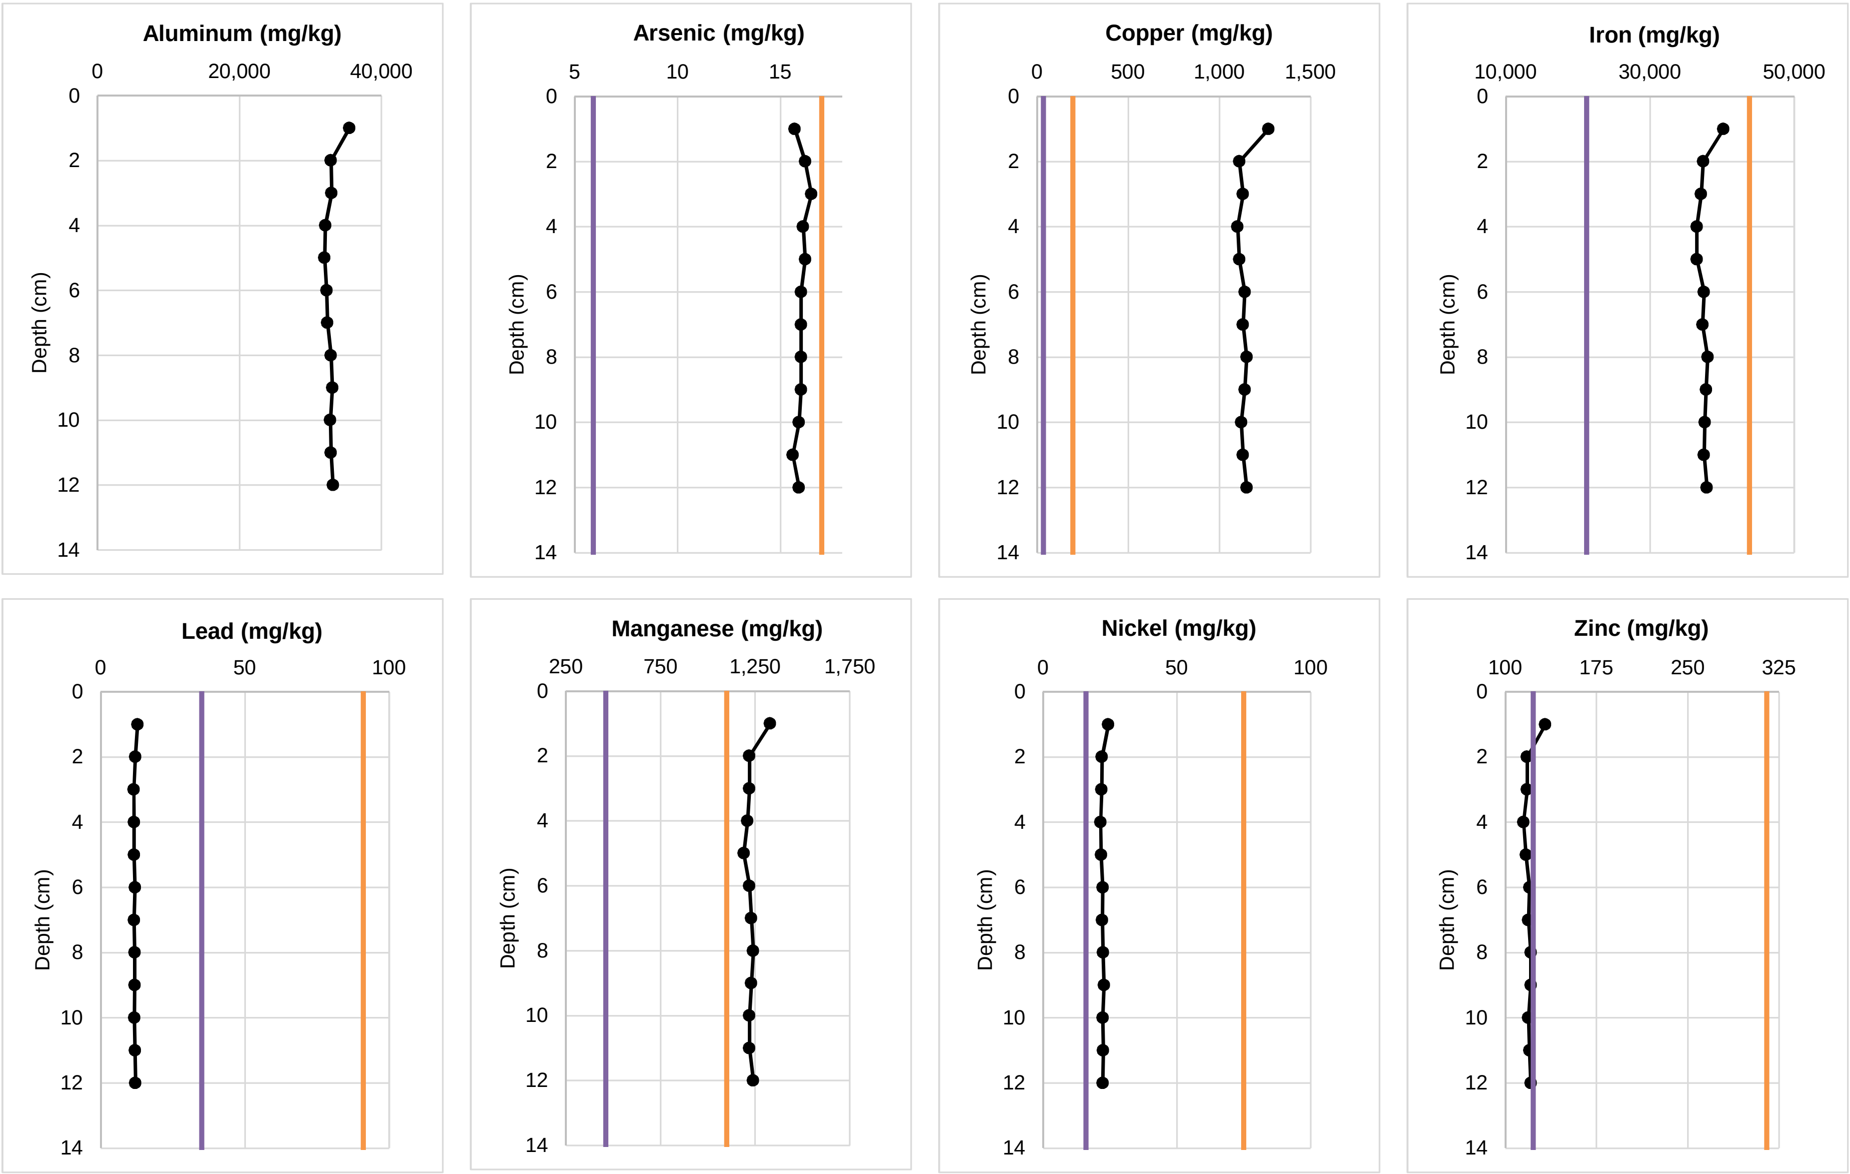

Figure 8.6: Sediment chemistry profiles of aluminum, arsenic, copper, iron, lead, manganese, nickel and zinc from the near-field station (QUL-PW-1) of Quesnel Lake, September 2014. Threshold Effect Level (TEL) is displayed in purple, while the Probable Effect Level (PEL) is in orange.

1 cm). The higher concentrations of these metals in the top-most sediment section suggested higher concentrations in the very fine particles that settled out last.

8.3.3 Sediment Pore Water Profiles

Sediment pore-water was evaluated on the basis of redox sensitive nitrogen and sulphur compounds as well as metal concentrations. Sediment pore-water profiles of nitrate and nitrite showed that there were low concentrations of nitrite evident in surficial sediment (Figure 8.7). The nitrite concentration was highest in the overlying water, suggesting that the source of nitrite was not from the sediment. It is more likely that nitrite, sourced from the overlying water, was diffusing into the mine-derived material such that by 3 cm depth there was no more detectable nitrite in sediment pore-water. If nitrite was occurring due to reduction of nitrate (i.e., sediment diagenesis), a profile of high concentrations of nitrite should also have a congruent decrease of nitrate concentration, which was not evident. The depth profile of sulphate also showed detectable concentrations throughout the core, and non-detectable concentrations of sulphide throughout the core. Therefore, there was no evidence of reducing conditions in the top 12 cm of the sediment core. This is a reasonable observation as the material collected from the streambed of Hazeltine Creek showed no evidence of reduced mineralogy such as pyrites or high levels of organic matter, but instead contained oxides and aluminosilicates (oxidized minerals; Appendix Table E.65).

The pore-water profiles of metal concentrations did not follow those of the sediment chemistry profiles (Figures 8.6 and 8.7). Metal concentrations were not highest at the top-most sediments (as with the sediment chemistry profiles), suggesting that the metals associated with clay-sized particles are less soluble than metals associated with particles from deeper in the core. Pore-water concentrations of copper, iron, lead, nickel, and to some extent, arsenic, manganese, zinc, and nitrate, showed some degree of elevation in concentration around 3 to 7 cm depth (Figure 8.7). Given the oxidizing conditions of the pore-water, it is likely that this increase was due to desorption. As silicon concentrations were also elevated from 3 to 7 cm depth, it is possible that the dissolved metals were associated with aluminosilicates which may also dissolve to some extent. Several aluminosilicate minerals were present in the tailings (e.g., feldspars, and plagioclase; SRK 2014, 2015). As the deposited materials were unconsolidated, the sediment particles were not completely compacted, and post-depositional processes would not have had enough time to establish. The increase in pore water concentrations at 3 to 7 cm depth may be a transient observation for these sediments. A separate evaluation of potential post-depositional stability indicated very low risk of metal mobilization (SRK 2015).

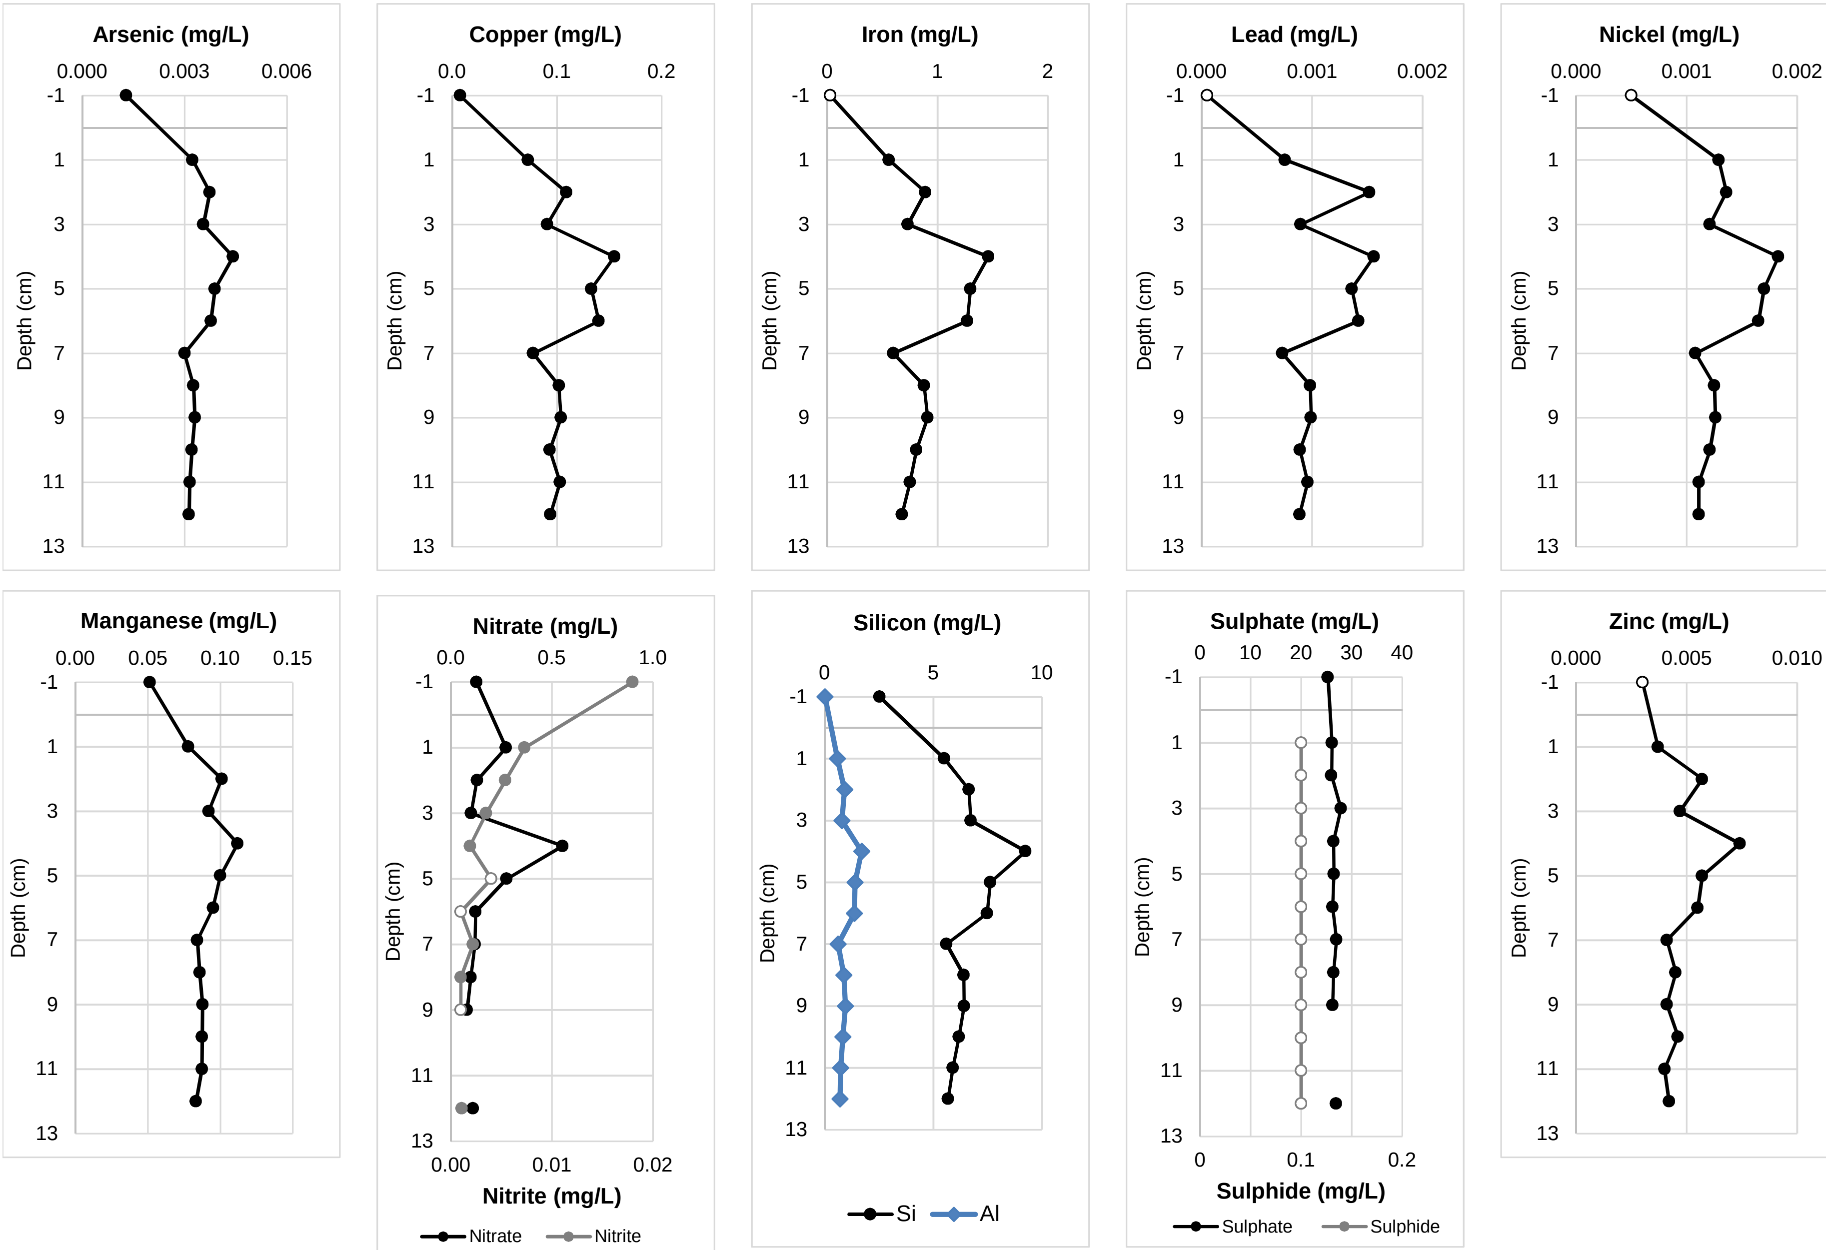

Figure 8.7: Pore water profiles of arsenic, copper, iron, lead, nickel, manganese, nitrate, nitrite, silicon, sulphate, sulphide and zinc from the near-field station (QUL-PW-2) of Quesnel Lake, September 2014. Open data markers (o) indicate that the concentration was below the Method Detection Limit (MDL).

[1] Analyte concentrations shown at a depth of -1 cm indicate concentrations in overlying water samples collected at QUL-PW-2.

8.4 Sediment Toxicity

Sediment toxicity testing indicated significantly reduced survival of the freshwater/brackish water amphipod *Hyalella azteca* only at the near-field area relative to concurrent laboratory controls and both references (Figure 8.8; Appendix Table F.1; Appendix Figure F.7). Absolute survival (i.e., non-normalized) at the near-field area was 76% and ranged from 84% to 96% at the far-field and far-far-field areas (Appendix Table F.10). Growth of *H. azteca* was significantly reduced at the upstream far-field area (PFF2; Figure 4.5) relative to laboratory controls and both references (Figure 8.8; Appendix Table F.1; Appendix Figure F.7). Survival of the freshwater midge *Chironomus dilutus* was significantly reduced relative to concurrent laboratory controls and both references at the near-field area and both far-field areas (Figure 8.8; Appendix Table F.1; Appendix Figure F.8). Absolute survival (i.e., non-normalized) was lowest at the downstream far-field station (PFF1), with survival of 58% compared to 68% at the near-field area and 76% at the upstream far-field (Appendix Table F.11). Growth of *C. dilutus* was significantly reduced at the near-field area only (area PNF) relative to laboratory controls and both references, but not at any other profundal areas (Figure 8.8; Appendix Table F.1; Appendix Figure F.8). Overall, the toxicity data indicate an apparent effect on survival of *H. azteca* and on survival and growth of *C. dilutus* at the near-field area. Reduced growth of *H. azteca* was observed at the upstream far-field area (highlighted primarily on the basis of a high growth rate in one laboratory control), and reduced survival (but not growth) of *C. dilutus* was observed at both far-field areas.

8.5 Benthic Invertebrate Community

Benthic invertebrate community samples from near-field, far-field and far-far-field profundal areas of Quesnel Lake were compared to two reference areas within Quesnel Lake (Table 4.1; Figure 4.5) in a Multiple Control-Impact (MCI) design. Samples were collected by petite ponar grab sampler at five stations per area.

8.5.1 Primary Metrics

Mean benthic organism densities (individuals/m^2) of the exposed areas (near-field, far-field and far-far-field) were significantly lower than reference area 1, but did not differ significantly from reference area 2 (40, 23 and 3.4 organisms/m^2 at the near-field, downstream far-field and upstream far-field, respectively; Figure 8.9; Appendix Tables G.22 and G.23). Taxon richness was significantly lower at the upstream far-field area than at either reference, and was supported by low diversity at this area (Figure 8.9; Appendix Tables G.22-G.23). There were no benthic invertebrates at 4 of 5 stations at

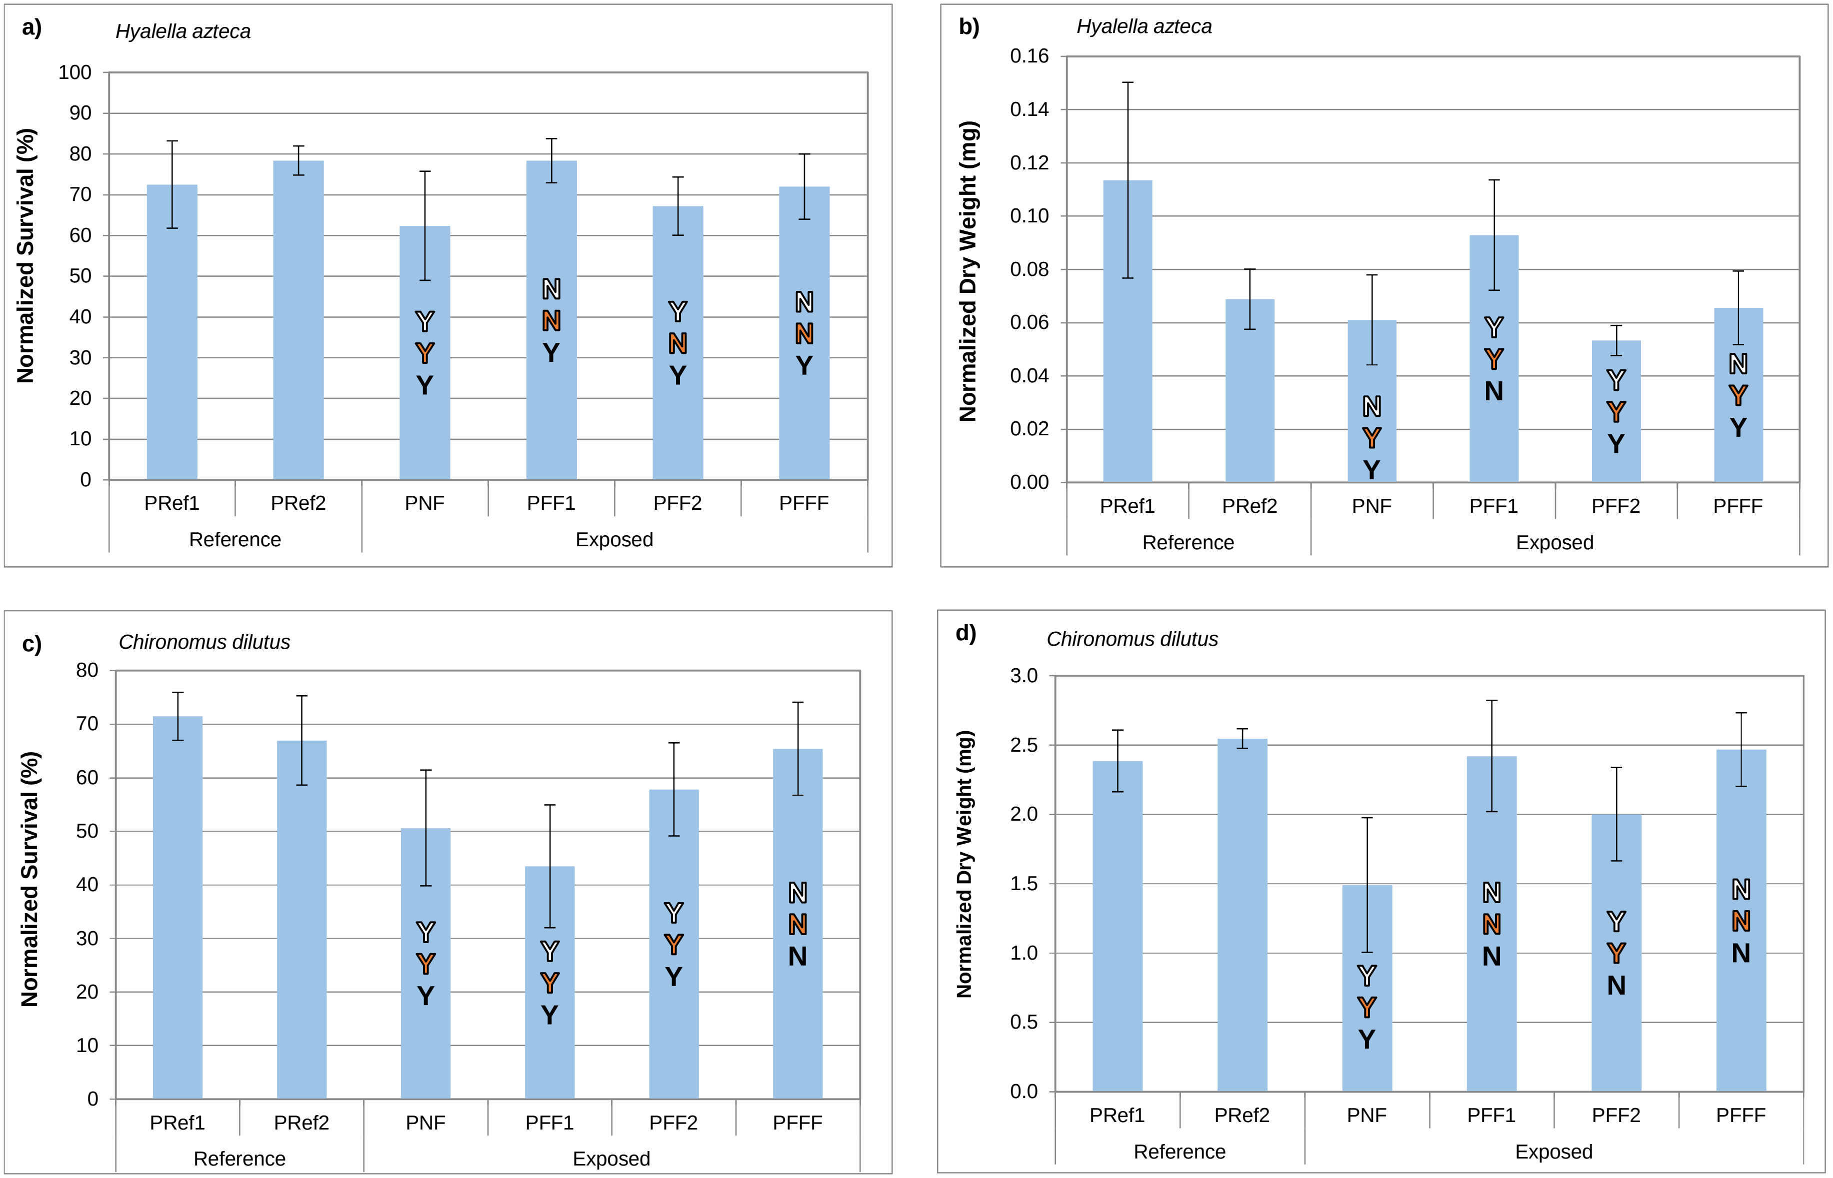

Figure 8.8: Toxicity tests results of Quesnel Lake profundal sediment on *Hyalella azteca* , a) Normalized Survival (%), b) Normalized Dry Weight (mg) and *Chironomus dilutus* c) Normalized Survival (%), d) Normalized Dry Weight (mg). Error bars represent standard deviation. Letters represent significant differences (Y) or no differences (N) between samples and the Control (Black), Reference 1 (Orange) and Reference 2 (White) ($p < 0.05$). Control results are not displayed.

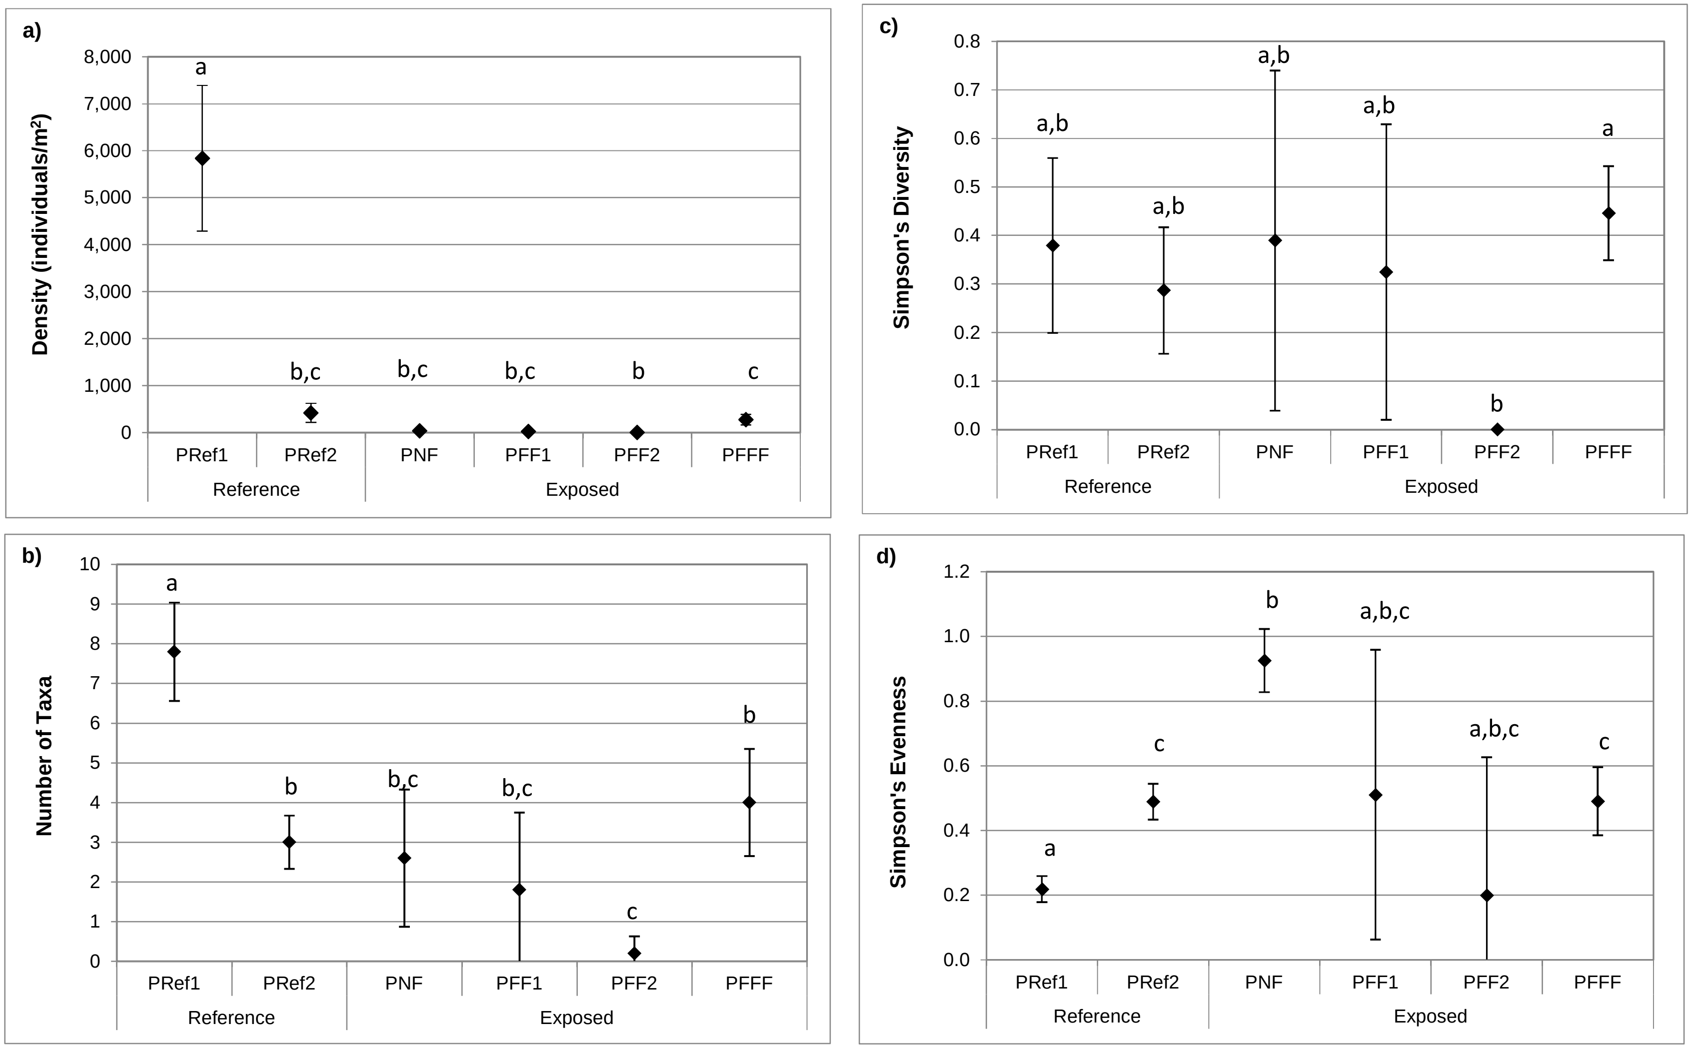

Figure 8.9: Comparison of a) Density, b) Number of Taxa, c) Simpson's Diversity and d) Simpson's Eveness, Mount Polley Mine 2014. Quesnel profundal area comparisons. Data represents area means and 90% confidence intervals. Different letters above data points indicate areas that were significantly different ($p < 0.1$).

the upstream far-field and only one chironomid species (*Heterotrissocladius*) was present at the remaining station (Appendix Tables G.23-G.24). Low number of taxa relative to reference can be indicative of a degraded benthic invertebrate community (Pielou 1974; Begon et. al. 1996). Lastly, Simpson's Evenness was significantly greater at the near-field exposed area than at both references (Figure 8.9; Appendix Table G.22). Simpson's Evenness is often lower at areas with few taxa than at areas with more taxa.

8.5.2 Community Composition

Dominant invertebrate taxon groups at the Quesnel Lake profundal areas were non-biting midges (Chironomidae), oligochaete worms, and mites (Acari), with lesser representation by biting midges (Ceratopogonidae), snails (gastropods), and clams/mussels (bivalves; Figure 8.10; Appendix Table G.23).

Bray-Curtis index of dissimilarity (BC index) was significantly greater at the near-field area and the far-field areas relative to both references (but not at the far-far-field area), indicating a difference in community composition (Figure 8.11; Appendix Table G.22). Community differences detected by the BC index are non-directional and not necessarily related to chemical exposure. That is, communities may be significantly dissimilar due to chemical effects or to natural factors (e.g., subtle habitat differences). Despite the differences detected using the BC Index, there were no statistically significant differences in the proportions of key taxa relative to both references, presumably due to high variability within areas (Figure 8.11; Appendix Table G.22). However, correspondence analysis confirmed the differences detected with BC Index, and these were largely relative to reference area 1 (Horsefly Bay), which had significantly greater CA-1 values than all other areas except the downstream far-field area (PFF1). CA axis 1 describes 41.3% of the spatial variance in benthic invertebrate community composition, with *Heterotrissocladius* (a chironomid of the sub-family Orthocladinae) providing the negative weighting and *Phaenopsectra* (a chironomid of the sub-family Chironominae) and *Bezzia*/*Palpomyia* (biting midges or no-see-ums of the family Ceratopognidae) providing the positive weighting (Appendix Table G.25). This CA axis primarily distinguishes Horsefly Bay on the basis of greater representation by the chironomid *Phaenopsectra* and the Ceratopogonids *Bezzia*/*Palpomyia* relative to other areas (Figure 8.11).

8.6 Correlation Analysis

Correlation analysis was conducted between the biological endpoints (sediment toxicity test endpoints and benthic invertebrate community endpoints) and dissolved oxygen, specific conductance, percent fines, sediment TOC content, sediment concentrations of

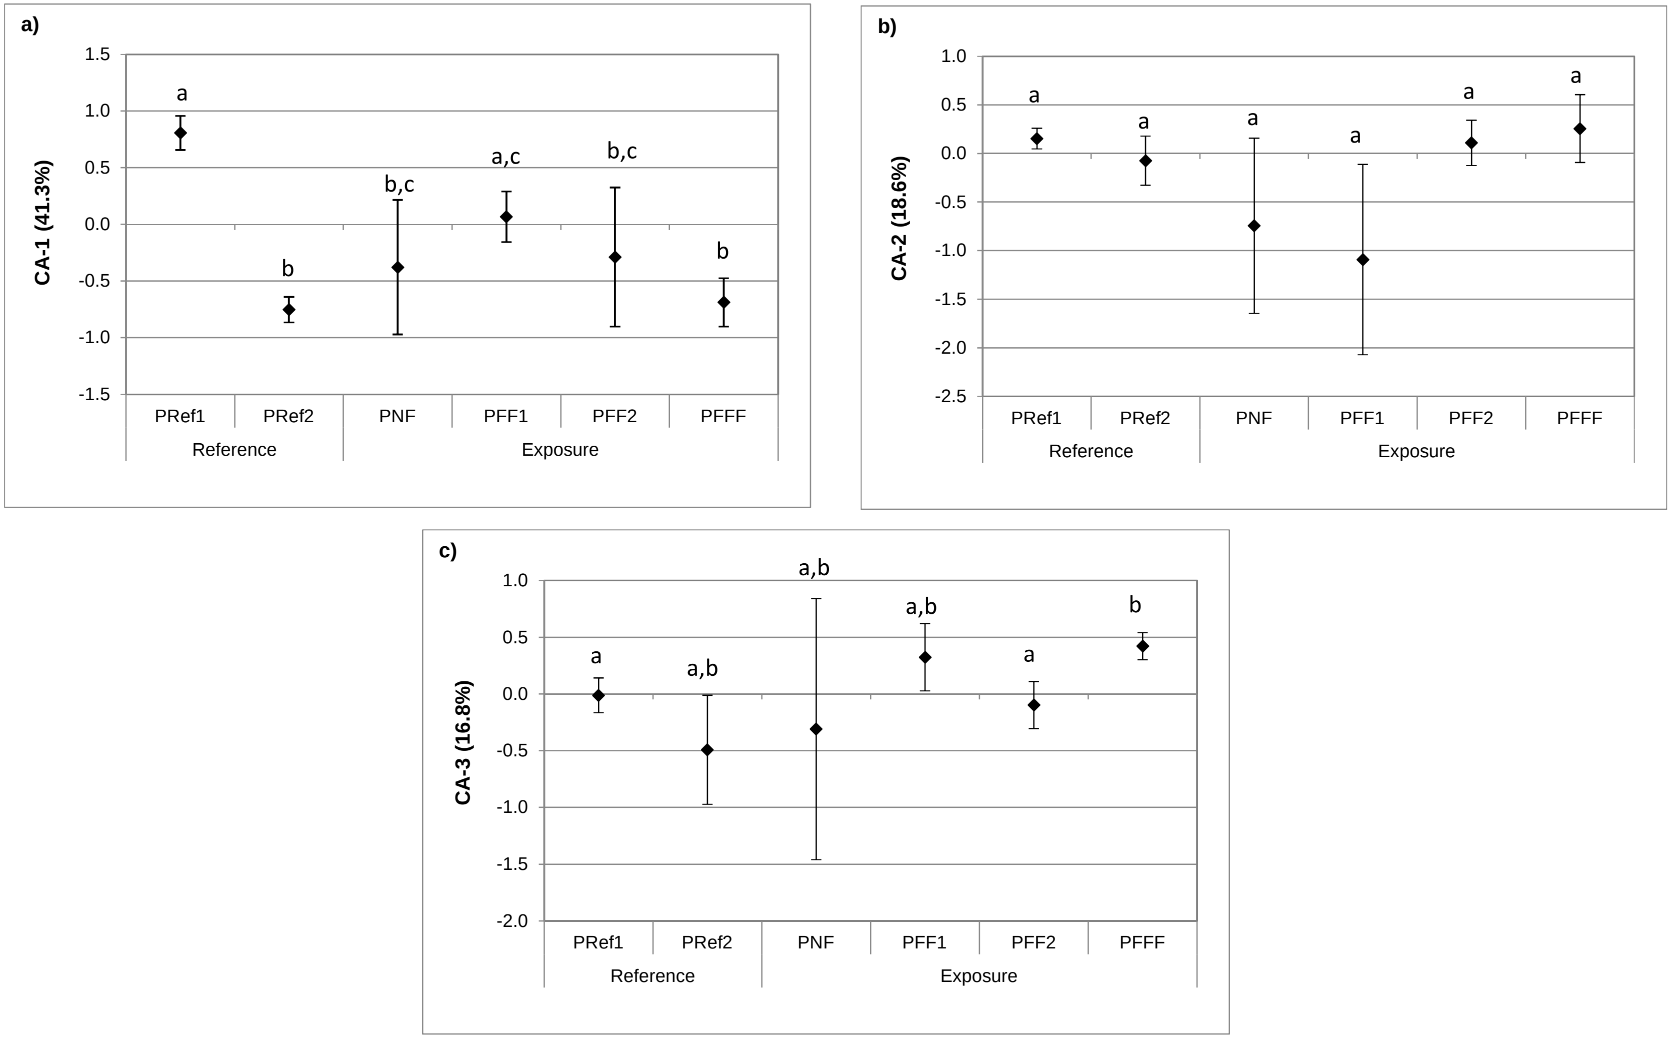

Figure 8.11: Comparison of d) CA-1 (41.3%), e) CA-2 (18.6%) and f) CA-3 (16.8%), Mount Polley Mine, 2014. Quesnel profundal area comparisons. Data represents area means and 90% confidence intervals. Different letters above data points indicate areas that were significantly different ($p < 0.1$).

POIs, IPs, PCA axes and selective copper extracts. There were no relationships between survival or growth of *H. azteca* and sediment physical or chemical characteristics at the Bonferroni-adjusted p-level; Table 8.8). Survival of *C. dilutus* was positively correlated with sediment TOC content and negatively correlated with copper in carbonate and easily reducible extracts (Table 8.8), which was similarly observed in littoral sediments (Section 7.5). Lastly, growth of *C. dilutus* was negatively correlated with copper, including copper in all four selective extracts, calcium, sodium and vanadium (Table 8.8). Although correlation does not necessarily indicate causation, the significant positive relationships to sediment TOC and the significant negative relationships between *C. dilutus* survival and growth versus POI and IP concentrations, including copper extracts suggest benefits of organic matter and/or toxic effects of metals.

A substantial number of relationships between benthic invertebrate community metrics and sediment chemistry were observed at the Bonferroni-adjusted p-level, particularly with density and Bray-Curtis index of dissimilarity (Table 8.8). Benthic invertebrate density was positively correlated with dissolved oxygen, sediment TOC and nickel concentration and negatively correlated with specific conductance, the proportion of fines, copper, calcium, sodium, strontium, as well as copper in the exchangeable, easily reducible, and organic phases (Table 8.8; Appendix Figure I.9). Number of taxa was negatively correlated with strontium and easily reducible copper (Table 8.8). Bray-Curtis index of dissimilarity was correlated with the same analytes that correlated with benthic density, but in the opposite direction indicating a consistent effect response (i.e., reduced density and increase Bray-Curtis index with low TOC and high POI concentrations; Table 8.8; Appendix Figure I.9). Percent Chironomidae were positively correlated with nickel and PCA-Axis 1 (representing the conditions at the far-far-field area and reference 2, both of which had relatively high proportions of Chironomidae; Table 8.8; Appendix Figure I.9). Lastly, benthic invertebrate community CA axis 1 was negatively correlated with arsenic and manganese (Table 8.8; Appendix Figure I.9). As previously indicated, CA axis 1 is primarily represented by the chironomid *Phaenopsectra* and the Ceratopogonids *Bezzia*/*Palpomyia* in the positive direction and the chironomid *Heterotrissocladius* in the negative direction and is mainly driven by the co-occurrence of high arsenic and manganese in the far-far-field area (not failure-related) and relatively higher associated abundance of *Heterotrissocladius* and lower abundance of *Phaenopsectra* and the Ceratopogonids (Appendix Figure I.9).

Table 8.8: Spearman's Rank Correlation results for correlation of toxicity test results and benthic invertebrate community metrics versus sediment physical characteristics, parameters of interest, indicator parameters, PCA axes scores, copper extracts (all in < 2mm sediment fraction) in Quesnel Lake profundal sampling areas, Mount Polley Mine, 2014 [1,2].

(Orange shading) Significant correlation; p-value < 0.0001 (Bonferroni corrected p-value for 432 comparisons among Table 8.8 and Appendix Table I.4).

(Grey shading) Correlation scatterplot inspected; p <0.01.

[1] Values < method detection limit (MDL) were used at the MDL for calculations. Normalized survival and growth are relative to associated laboratory control.

[2] For sampling areas where 5 toxicity field replicates were analysed for each station (Sampling areas PRef1, PNF, and PFF1), mean survival and growth measures (of the 5 replicates per station) were used for correlations with individual sediment chemistry measures from each station.

[3] Copper extract results for sampling areas PRef2, PFF2, and PFF are for a single composite sample. As a result, the single copper value available for each fraction was used in correlations with each of the 5 toxicity replicates from each of these sampling areas.

NA = Correlation was not performed between these two parameters.

Note: n=30 for all correlations.

8.7 Data Integration, Summary and Spatial Extent

As also observed in the Quesnel Lake littoral areas, sediment total organic carbon content was low in exposed areas and increased to concentrations similar to reference with distance from the mouth of Hazeltine Creek. Sediment collected from influenced profundal areas of Quesnel Lake following the dam failure was characterized by concentrations of copper greater than the SQG PEL and reference concentrations that decreased with distance from the mouth of Hazeltine Creek, and by concentrations of a number of IPs (calcium, sodium, strontium, tin and vanadium) that also decreased with distance from the mouth of Hazeltine Creek. A number of additional metals were elevated to concentrations greater than SQG TELs and reference at the far-far-field area only, which suggest that they were not failure-related. Sediment geochemical evaluations indicated that, for most POIs (including those identified on the basis of sediment quality data from Hazeltine Creek, Polley Lake and the Quesnel Lake littoral zone) and IPs, concentrations were mostly in the residual phase, a fraction that is not considered mobile or biologically available. However, copper was a notable exception, with the majority occurring in the "organic" phase (which appears to be mineral), and with concentrations in the exchangeable, carbonate and easily reducible phases at near-field and far-field areas greater than reference. Separate integrated consideration of mineralogy, sequential extraction results and mineral solubility indicates that these forms would not be mobile under environmentally realistic conditions (SRK 2015).

Sediment stratigraphy evaluation at the near-field area indicated little vertical variation in sediment chemistry; only slightly higher concentrations of a number of failure-related metals in surficial sediments. Sediment and pore-water analysis indicated that sediments were under oxidizing conditions (there was no evidence of reducing conditions), and therefore, metals are likely to remain associated with particulates. Porewater metal concentrations did not mirror sediment concentrations and were relatively elevated at 3 to 7 cm sub-surface. Sediments were not fully compacted when the cores for sediment and pore-water chemistry were collected. Separate evaluation of potential post-depositional mobility indicated very low risk of metal mobilization (SRK 2015).

Sediment toxicity testing indicated an effect on survival of *H. azteca* and on survival and growth of *C. dilutus* at the near-field area relative to reference and laboratory controls. Reduced growth of *H. azteca* was observed at the upstream far-field area (driven primarily on the basis of a high growth rate in one laboratory control), and reduced survival (but not growth) of *C. dilutus* was observed at both far-field areas. Benthic invertebrate community assessment indicated that the benthic invertebrate community of the Quesnel Lake profundal zone (including reference areas) was composed of few organisms. The upstream far-field area had no organisms present at four of five stations. Density of the near-field and far-field areas was low (<50 organisms/m^2), and the upstream far-field area had significantly lower taxon richness than both reference areas. Community composition at the near-field and far-field areas differed significantly from both references. However, compositional differences between reference areas were as large as those between exposed and reference areas.

Correlation analysis indicated some positive relationships between biological endpoints (survival and growth of the toxicity test organisms and benthic invertebrate community density, taxon richness, diversity, evenness and community composition) and dissolved oxygen (benthic invertebrate community only) and sediment total organic carbon content. There were negative relationships between the biological endpoints and specific conductance (benthic invertebrate community only) and concentrations of a number of POIs and IP, including copper in selective extracts. As the positive influence of dissolved oxygen and TOC cannot be separated from potential negative effects due to elevated POI and IP concentrations, it is uncertain whether the effects are physical or chemical, but they are nonetheless related to the tailings dam failure.

Overall, an impact of the dam failure was evident on sediment quality of the near-field and far-field profundal areas of Quesnel Lake, with sediment quality improving with distance from the source. As at other locations (Hazeltine Creek, Polley Lake, and Quesnel Lake littoral), copper represents the analyte of greatest concern, both with respect to its absolute concentration relative to guidelines and its geochemical partitioning. Sediment stratigraphy evaluation indicated that sediments were oxidizing with a slight surface enrichment resulting from depositional rather than post-depositional processes. Sediment toxicity testing indicated effects to both test organisms at the near-field area and effects to *C. dilutus* survival (but not growth) at both far-field areas. Benthic invertebrate communities at all profundal areas (including reference areas) were composed of few organisms, but density of the near-field and far-field areas was particularly low as was taxon richness at the upstream far-field area which had significantly lower taxon richness than both reference areas. Community composition at the near-field and far-field areas differed significantly from both reference areas. Most benthic invertebrate community endpoints, including community composition, differed significantly between reference areas (indicating high natural variability in Quesnel Lake profundal areas). Correlation analysis suggested that the biological effects were failure-related, but it is uncertain whether the effects were physical (due to smothering and/or low dissolved oxygen and low TOC content) or chemical. Both physical observations and concentrations of POIs and IPs indicate that spatial extent of the tailings dam failure on Quesnel Lake profundal sediment quality extends through the far-field areas and covers a substantial linear distance (on the order of 7.5 km).

9.0 QUESNEL RIVER

Impact characterization in the Quesnel River included benthic invertebrate community characterization and benthic invertebrate tissue chemistry, supported by water quality data and physical measurements (Figure 4.6). The Quesnel River is erosional and no areas of sediment deposition were identified during sampling and therefore impact characterization did not include sediment. Data Quality Assessment (DQA; Appendix C with supporting data in Appendix J) indicated that water chemistry data, benthic invertebrate community data and benthic invertebrate tissue chemistry data were of good quality and can therefore be used confidently in impact characterization. Samples were collected from three areas upstream of the Cariboo River confluence (QUR1, QUR2 and QUR3) and three areas downstream of the Cariboo River confluence (QUR4, QUR5 and QUR6), and were compared to either two or three reference areas (Cariboo River [CAR], Clearwater River [CLR] and, for tissue chemistry only (due to habitat differences), Blackwater Creek [BLC]; Figure 4.6) in a combination Multiple Control-Impact (MCI) design and gradient design (the latter evaluating conditions in relation to distance from Quesnel Lake). Samples were collected by kick net at three stations per area.

9.1 Supporting Water Quality

No physical water quality characteristics exceeded British Columbia Water Quality Guidelines for the protection of aquatic life (BCWQG) at any Quesnel River or reference areas (Table 9.1). Conductivity, hardness, pH, and total suspended solids (TSS) were highest and lowest at Blackwater Creek (BLC) and the Clearwater River (CLR) reference areas, respectively. Turbidity and total dissolved solids (TDS) were higher in the Quesnel River downstream areas (QUR4, QUR5 and QUR6) relative to the upstream areas and reference areas (Table 9.1). No anions or nutrients exceeded BCWQG at any Quesnel River or reference area. Similarly, no reference area had total or dissolved metals above BCWQG; however, Quesnel River downstream areas QUR4 and QUR5 had concentrations of chromium, copper and iron greater than BCWQG in apparent association with higher turbidity (Table 9.1). There were no instances of dissolved metal concentrations greater than BCWQG.

Principal components analysis of total metals resulted in the first two axes explaining more variation in the original dataset than by chance alone. PCA axis-1 and PCA axis-2 explained 62.0% and 31.0% of the total extracted variance, respectively (Appendix Table I.5). PCA axis-1 separated Quesnel River downstream areas from Quesnel River upstream and reference areas along a high to low metal concentration gradient consisting

Table 9.1: Water chemistry results from benthic invertebrate sampling stations on the Quesnel River, Mount Polley Mine, October 2014.

(Shaded/bold) Concentration exceeds BCWQG for Aquatic Life.

[1] British Columbia Water Quality Guidelines (BCMOE 2015a, 2015b). All guidelines that are dependent on other parameters (ammonia, copper, fluoride, lead, manganese) were calculated based on most the conservative values observed in this dataset (hardness = 38.8 mg/L, chloride = <0.50 mg/L, pH = 8.12, and temperature = 13°C)

[2] Cadmium guideline is for dissolved cadmium concentrations (BCMOE 2015b).

[3] Applies to chromium as Cr (IV); guideline for Cr(III) is 0.0089 mg/L.

[4] Total nickel guideline value is for acute exposure, as described in guideline document (CCREM 1987)

[a] guidelines for turbidity, TSS and DOC are for induced values above reference or background

of titanium, cobalt, aluminum, chromium, zinc, nickel, iron, barium, lithium, manganese, and vanadium (Figure 9.1; Appendix Tables I.5-I.6). PCA axis-2 separated reference area BLC from the other eight study areas along a metals gradient consisting of silicon, magnesium, and molybdenum (Figure 9.1; Appendix Tables I.5-I.6). Principal components analysis of dissolved metals resulted in only the first axis explaining more variation in the original dataset than by chance alone, which explained 69.5% of the total extracted variance. Reference areas CLR and CAR and the upstream areas had similar PCA axis-1 values, which separate slightly from the downstream areas and greatly from reference area BLC along a metal concentration gradient consisting of barium, lithium, uranium, arsenic, and magnesium (Figure 9.2; Appendix Tables I.7-I.8).

Overall, water quality data collected at the time of benthic invertebrate community sampling demonstrated that upstream water quality was more similar to reference than downstream water quality. Although several POIs were identified in principal components analysis (e.g., iron, manganese and nickel), a number of others (including copper) and were not. In addition, copper concentrations and concentrations of the PCA axis 1 metals were higher downstream in the Quesnel River than upstream, suggesting little, if any, failure-related influence on water quality. This is consistent with the findings of a comprehensive evaluation of the impact of the tailings dam failure of receiving water quality (Golder 2015). Lastly, it was also apparent that the Blackwater Creek reference area (BLC) had a different mixture of metals and nutrients than the eight other study areas, which was likely due to the specific characteristics of its drainage basin (e.g., physiography, geology, ecosystem type).

9.2 Benthic Invertebrate Community

9.2.1 Primary Metrics

Benthic organism abundance (individuals/1 minute kick) was significantly greater at all three Quesnel River upstream areas (QUR1, QUR2 and QUR3) than at both reference areas (Table 9.2; Figure 9.3; Appendix Tables I.9-I.10). Mean benthic organism abundances at all three downstream areas (QUR4, QUR5 and QUR6) were not significantly different than reference area CLR, and only QUR4 differed significantly (lower density) from reference area CAR. Mean benthic organism abundance was highest at QUR1 (1,005 individuals/1 minute kick) and lowest at QUR4 (26 individuals/1 minute kick). Total abundance should be interpreted cautiously as differences (increase or decrease) are not necessarily an indication of impairment, and the kick and sweep method used in this study is semi-quantitative (Merritt *et al*. 2008) and best suited to assess data in terms of relative abundance.

(Grey shading) Indicates a significant difference between reference and exposed area. Values indicate the magnitude of difference as the number of reference standard deviations.

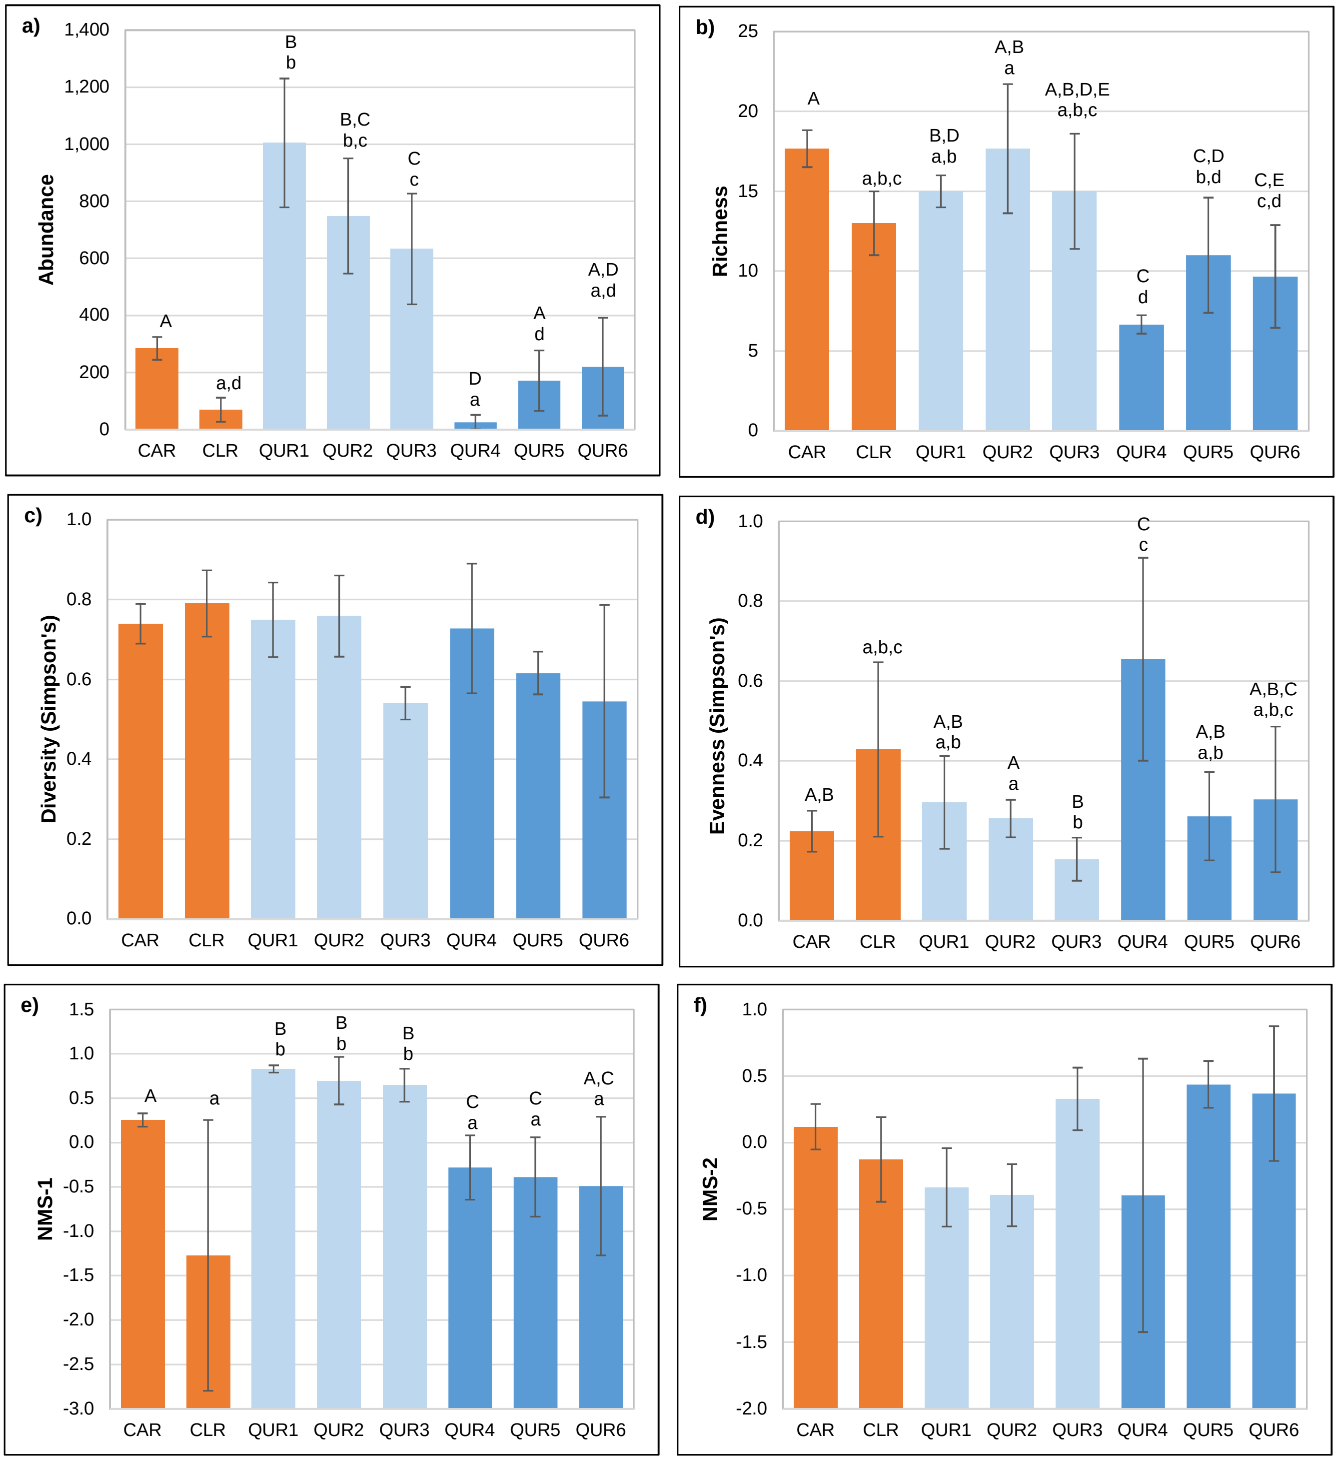

Figure 9.3: Primary benthic invertebrate metrics for Quesnel River areas (blue) and two reference areas (orange) located on Cariboo and Clearwater Rivers. Mean values ± one standard deviation are presented, Mount Polley Mine, October 2014.

Letters above whiskers identify statistical differences relating to the Cariboo River with Quesnel River ANOVA (uppercase letters) and Clearwater River with Quesnel River ANOVA (lower case letters). Areas that do not share a common letter are statistically different, and no letter indicates non-significant ANOVA. Light and dark blue colouring represents upper and lower reaches of the Quesnel River, respectively.

Mean area taxon richness of the Quesnel River upstream areas was similar to the Clearwater River reference area (CLR; Table 9.2; Figure 9.3). Upstream areas QUR2 and QUR3 were similar to the Cariboo River reference area (CAR), however upstream area QUR1 had significantly lower richness (Table 9.2; Figure 9.3). Mean area richness of all downstream areas was significantly lower than reference area CAR; however, only downstream area QUR4 had significantly different (lower) taxon richness than reference area CLR (Figure 9.3). Mean taxon richness was highest at reference area CAR (17.7) and lowest at Quesnel River downstream area QUR4 (6.7).

Mean Simpson's diversity did not differ among the nine study areas (Table 9.2; Figure 9.3). Mean Simpson's diversity was highest at reference area CLR (0.79) and lowest at Quesnel River upstream area QUR3 (0.54). Mean Simpson's evenness was similar at all Quesnel River areas relative to both reference areas with the exception that downstream area QUR4 had significantly higher evenness values than reference area CAR. Mean Simpson's evenness value was highest at downstream area QUR4 (0.65) and lowest at QUR3 (0.15).

9.2.2 Supporting Metrics

Dominant taxon groups (i.e., relative abundance ≥ 5%) encountered among all Quesnel River and reference areas included Ephemeroptera (mayflies), Plecoptera (stoneflies), Trichoptera (caddisflies) and/or Diptera (true flies; Figure 9.4), the latter of which were represented primarily by Chironomidae (non-biting midges). On average, metal-sensitive Ephemeroptera composed greater than 50% of the benthic invertebrate community at all study areas except the two upper-most Quesnel River areas (i.e., QUR1 and QUR2), where mean relative abundance of this group was less than 40% (Figure 9.4). The relative abundance of Ephemeroptera was significantly lower at the QUR1 and QUR2 areas compared to the CAR reference area (Table 9.2; Figure 9.5; Appendix Table I.11; Appendix Figure I.11). However, no significant difference in the relative abundance of this group was indicated at QUR1/QUR2 compared to the CLR reference area (Table 9.2; Figure 9.5). In addition, the absolute abundance (i.e., number of organisms per 1-minute kick sample) of Ephemeroptera was highest at the Quesnel River upstream areas. The latter two results suggested no failure-related impact to benthic invertebrates downstream of Quesnel Lake.

The relative abundance of Plecoptera, which are moderately sensitive to metals, did not differ significantly between any of the Quesnel River study areas compared to the CAR reference (Table 9.2; Figure 9.5). In contrast, Plecoptera relative abundance was significantly higher at upstream area QUR2 and all downstream areas (i.e., QUR4, QUR5

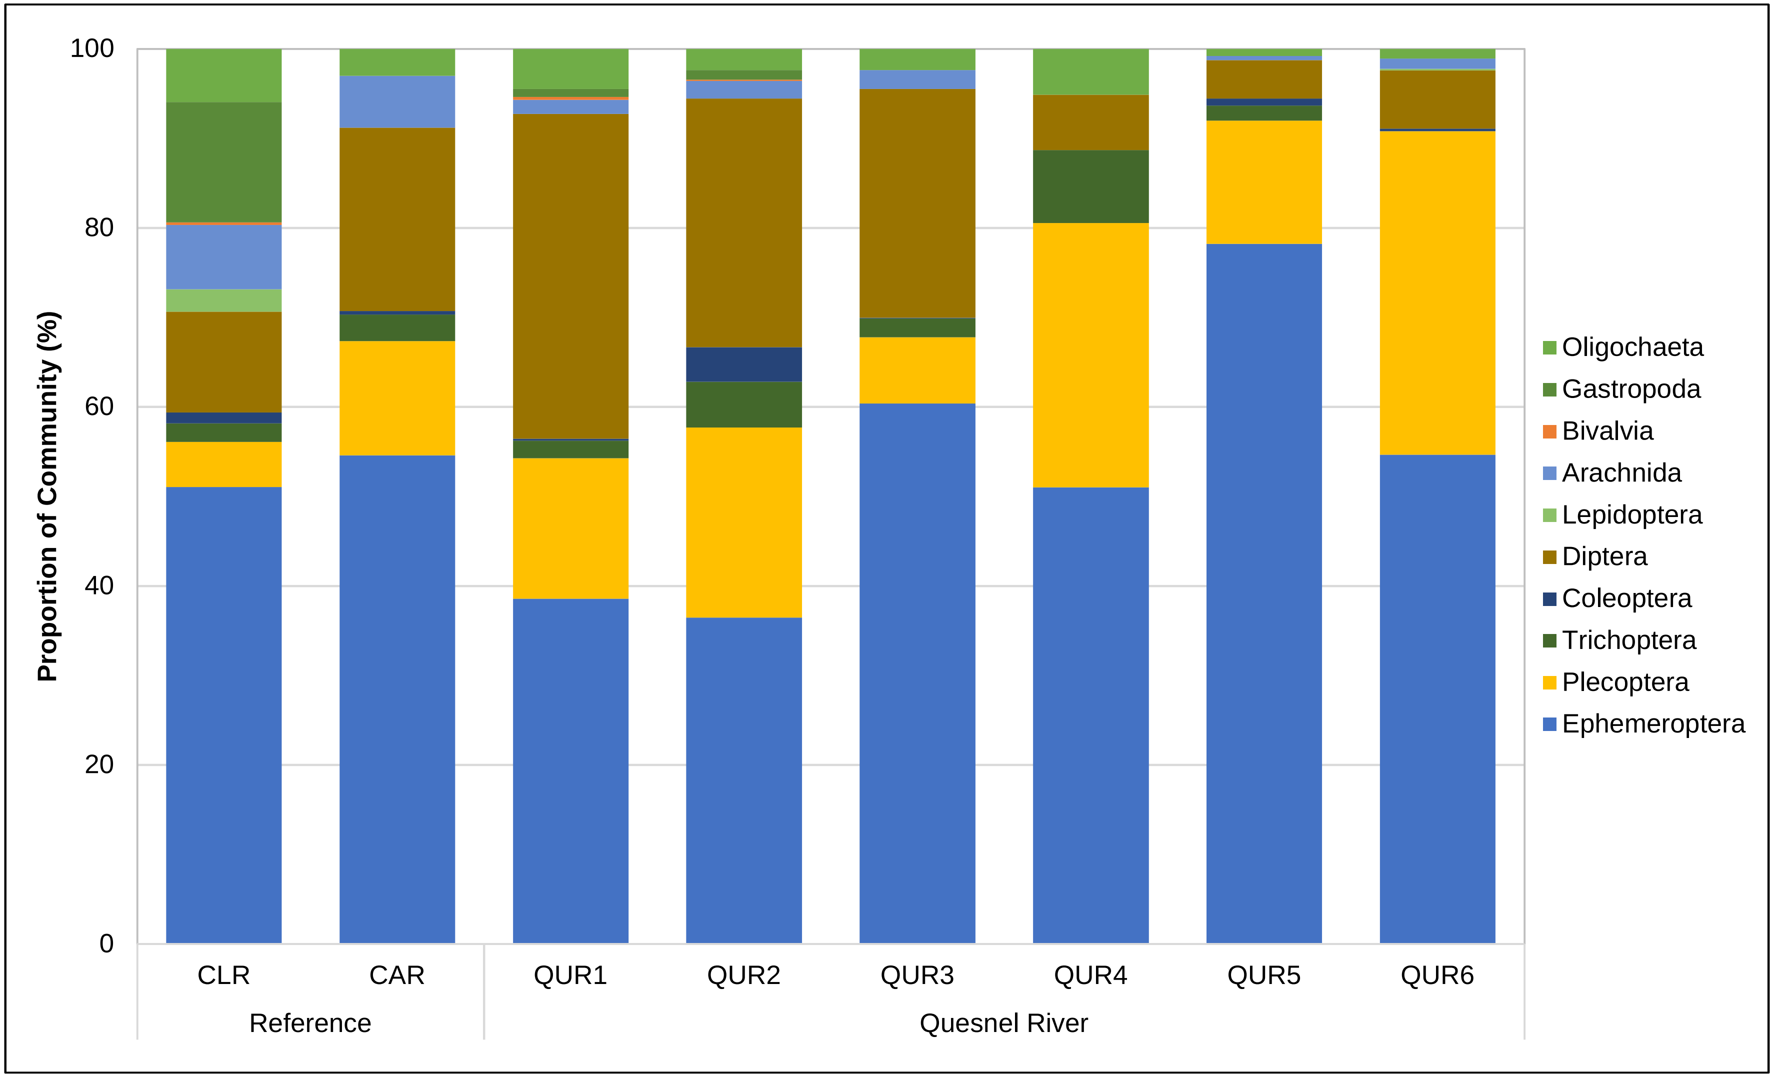

Figure 9.4: Relative mean proportions of major benthic invertebrate taxon groups within the Quesnel River and associated reference areas, Mount Polley Mine, 2014. Blackwater Creek (BLC) was not sampled for community structure as the substrate was not appropriate for comparison with the other areas.

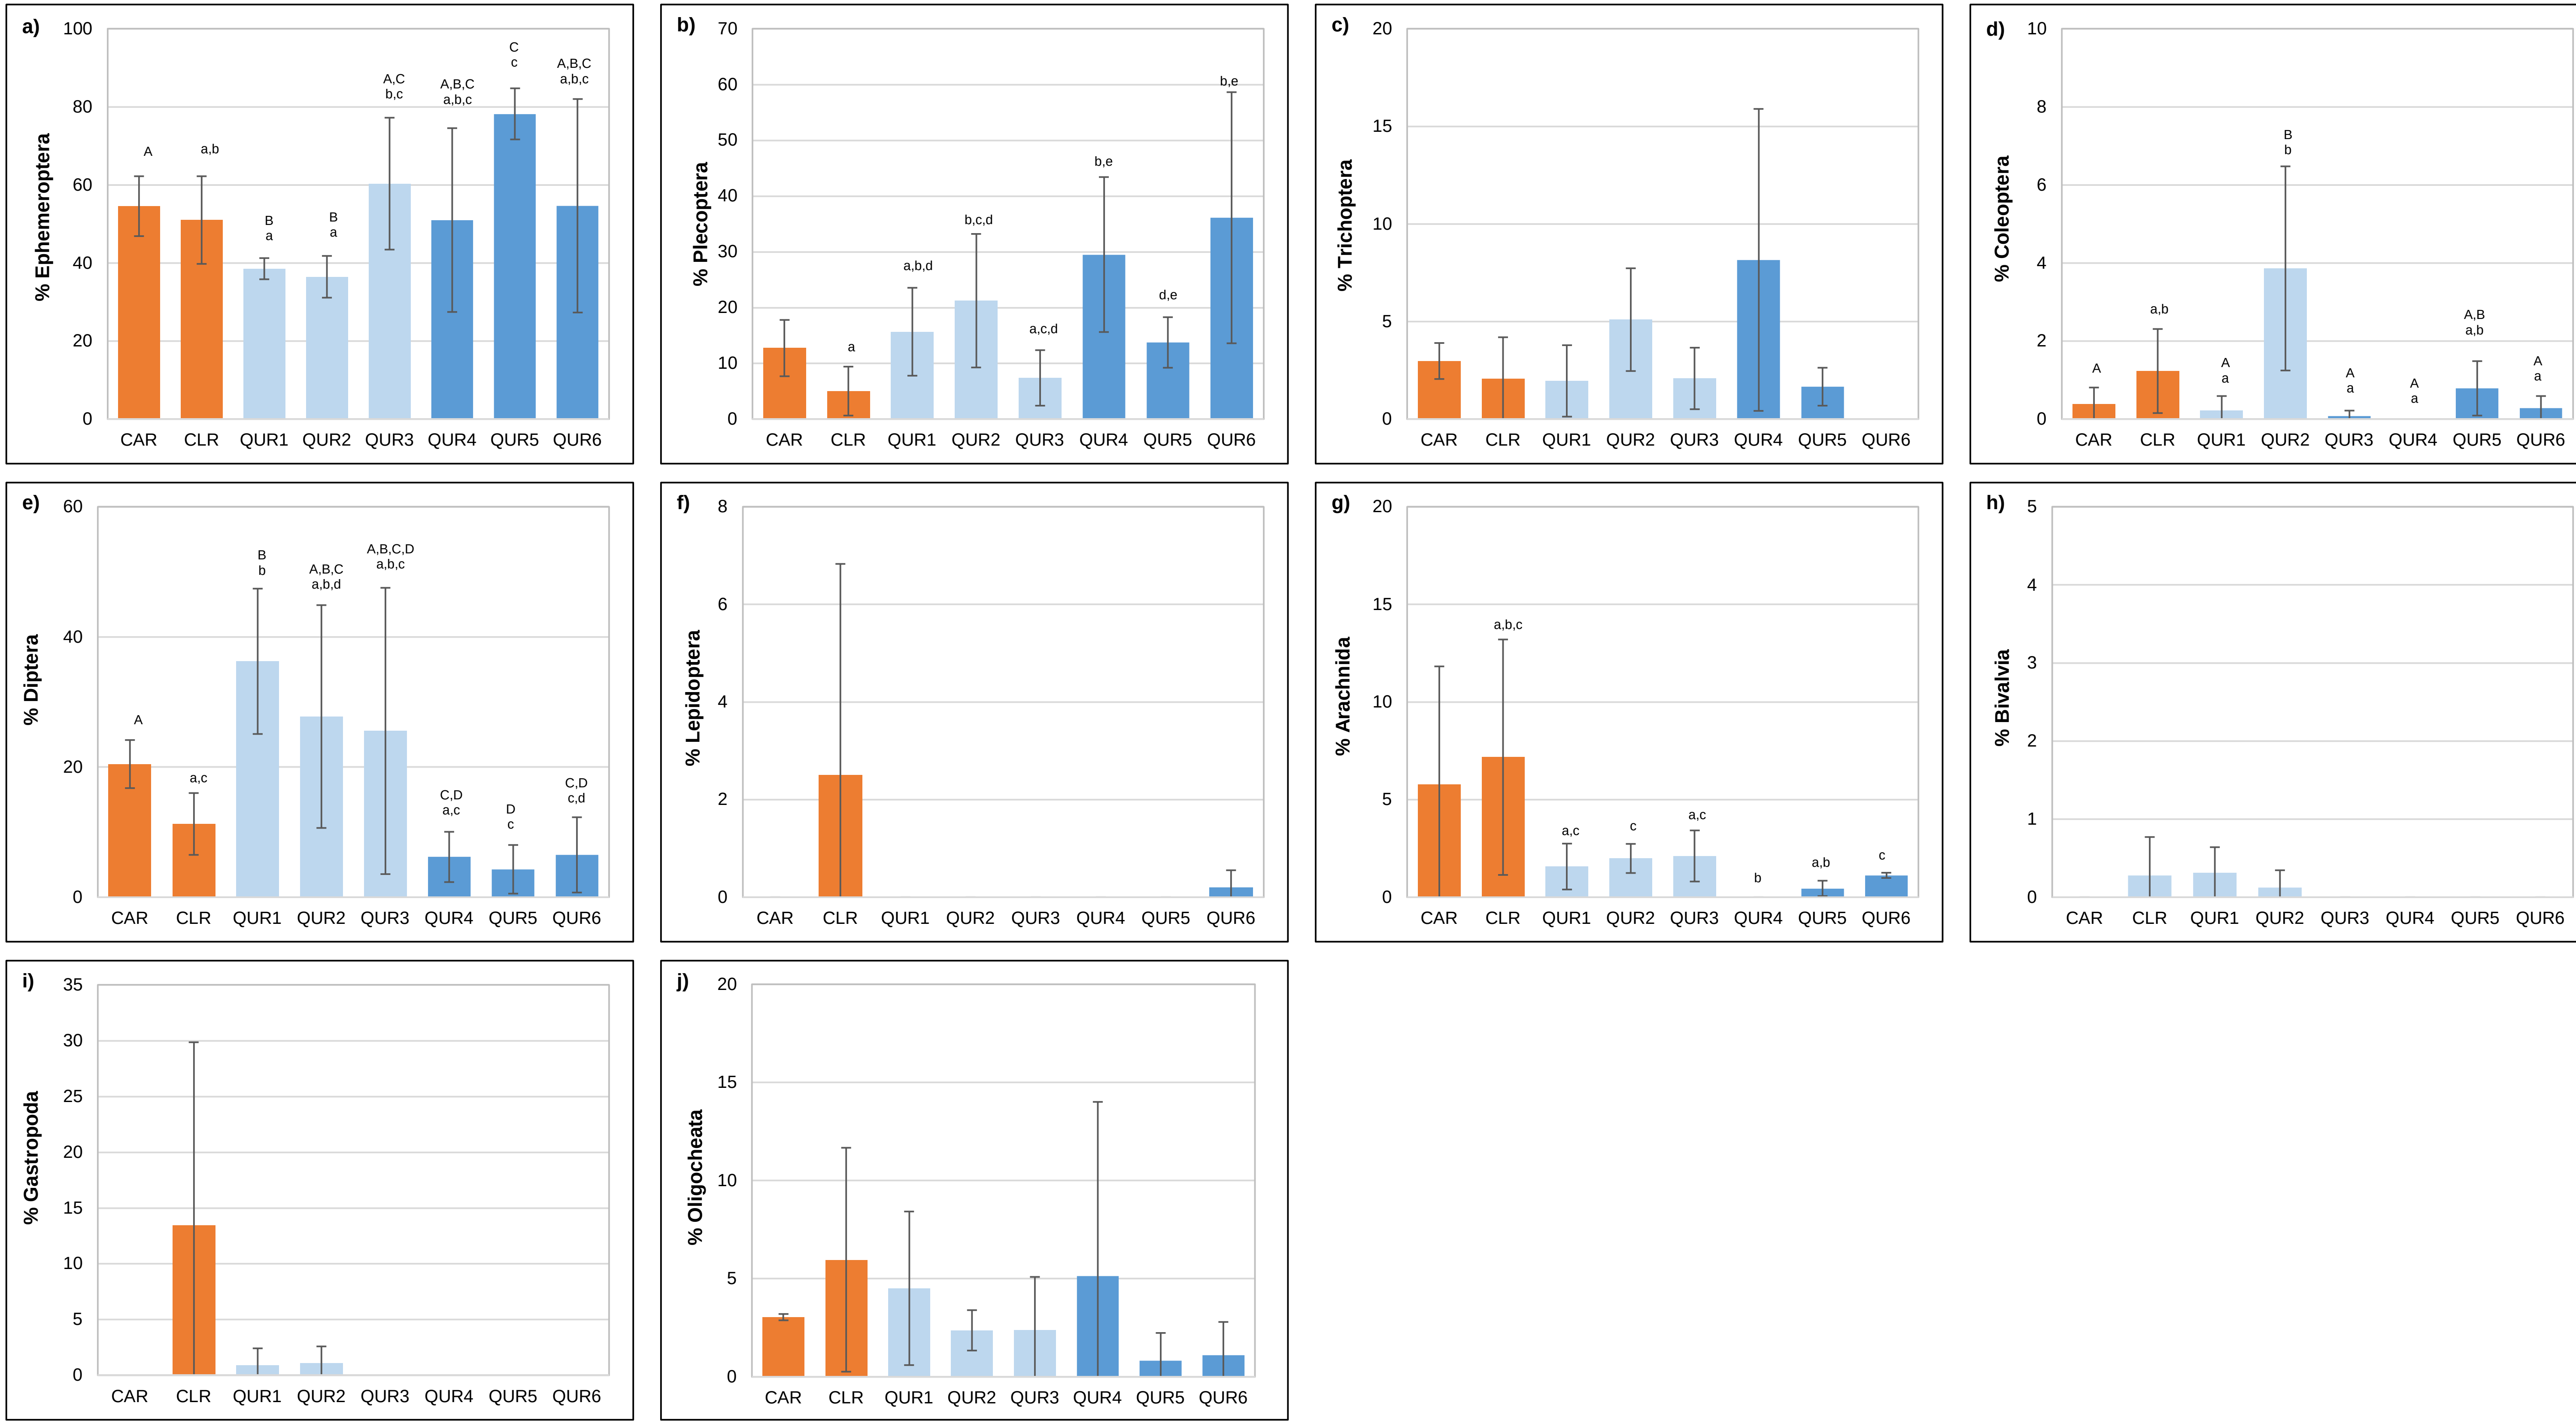

Figure 9.5: Major benthic invertebrate groups for Quesnel River areas (blue) and two reference areas (orange) located on Cariboo and Clearwater Rivers. Mean values ± one standard deviation are presented, Mount Polley Mine, October 2014.

Letters above whiskers identify statistical differences relating to the Cariboo River with Quesnel River ANOVA (uppercase letters) and Clearwater River with Quesnel River ANOVA (lower case letters). Areas that do not share a common letter are statistically different, and no letter indicates non-significant ANOVA. Light and dark blue colouring represents upper and lower reaches of the Quesnel River, respectively.

and QUR6) compared to the CLR reference area (Table 9.2; Figure 9.5; Appendix Table I.12; Appendix Figure I.12). No significant differences in the relative abundance of Trichoptera, which also show moderate sensitivity to metals, were indicated between any of the QUR upstream or downstream areas compared to either of the CAR or CLR reference areas (Table 9.2; Figure 9.5). Similar relative abundance, or significantly higher relative abundance, of moderately metal-sensitive Plecoptera and Trichoptera groups at QUR study areas compared to the reference area(s) suggested that, similar to comparisons of metal-sensitive Ephemeroptera among the study areas, no failure-related impact to benthic biota occurred in the Quesnel River.

Relative abundance of Diptera was significantly higher than reference only at the Quesnel River upstream area (QUR1; Table 9.2; Figure 9.5). Most taxa within the order Diptera are considered relatively metal tolerant. However, members of the midge tribe Tanytarsini and sub-family Diamesinae inhabiting erosional lotic habitat generally exhibit high sensitivity to metals (e.g., Barbour et al. 1999). Because the absolute abundance of Tanytarsini and Diamesinae midges was highest at Quesnel River upstream areas including QUR1, higher relative abundance of Diptera at QUR1 compared to the CAR and CLR reference areas was not consistent with a metal-related response. Although the relative abundance of Diptera also differed significantly between the Quesnel River downstream areas and the CAR reference area, higher relative abundance of this group at the upstream areas and no differences in Diptera relative abundance in downstream areas compared to the CLR reference suggested no adverse failure-related influences on this group at the Quesnel River study areas. The biggest difference between the two reference areas was the occurrence of Gastropoda and Lepidoptera at CLR and the absence at CAR (Figure 9.5).

Analysis of benthic invertebrate community structure was supported by non-metric multidimensional scaling (NMS), which resulted in a stable 2-dimensional solution (Figure 9.6), with the variation represented by the NMS axes significantly greater than that explained by chance alone (i.e., Monte Carlo p-value less than 0.05). The first two NMS axes captured the majority (i.e., 84.2%) of the total variation in the benthic invertebrate community data set. The first NMS axis (NMS-1) explained 67.3% of the total variation, with the mean NMS-1 area scores significantly greater at each of Quesnel River upstream areas (QUR1, QUR2 and QUR3) than both the Cariboo River (CAR) and Clearwater River (CLR) reference areas (Table 9.2; Figure 9.3; Appendix Table I.13). No Quesnel River downstream area had different NMS-1 area scores than either reference area, with the exception that QUR4 and QUR5 had significantly lower scores than reference area CAR

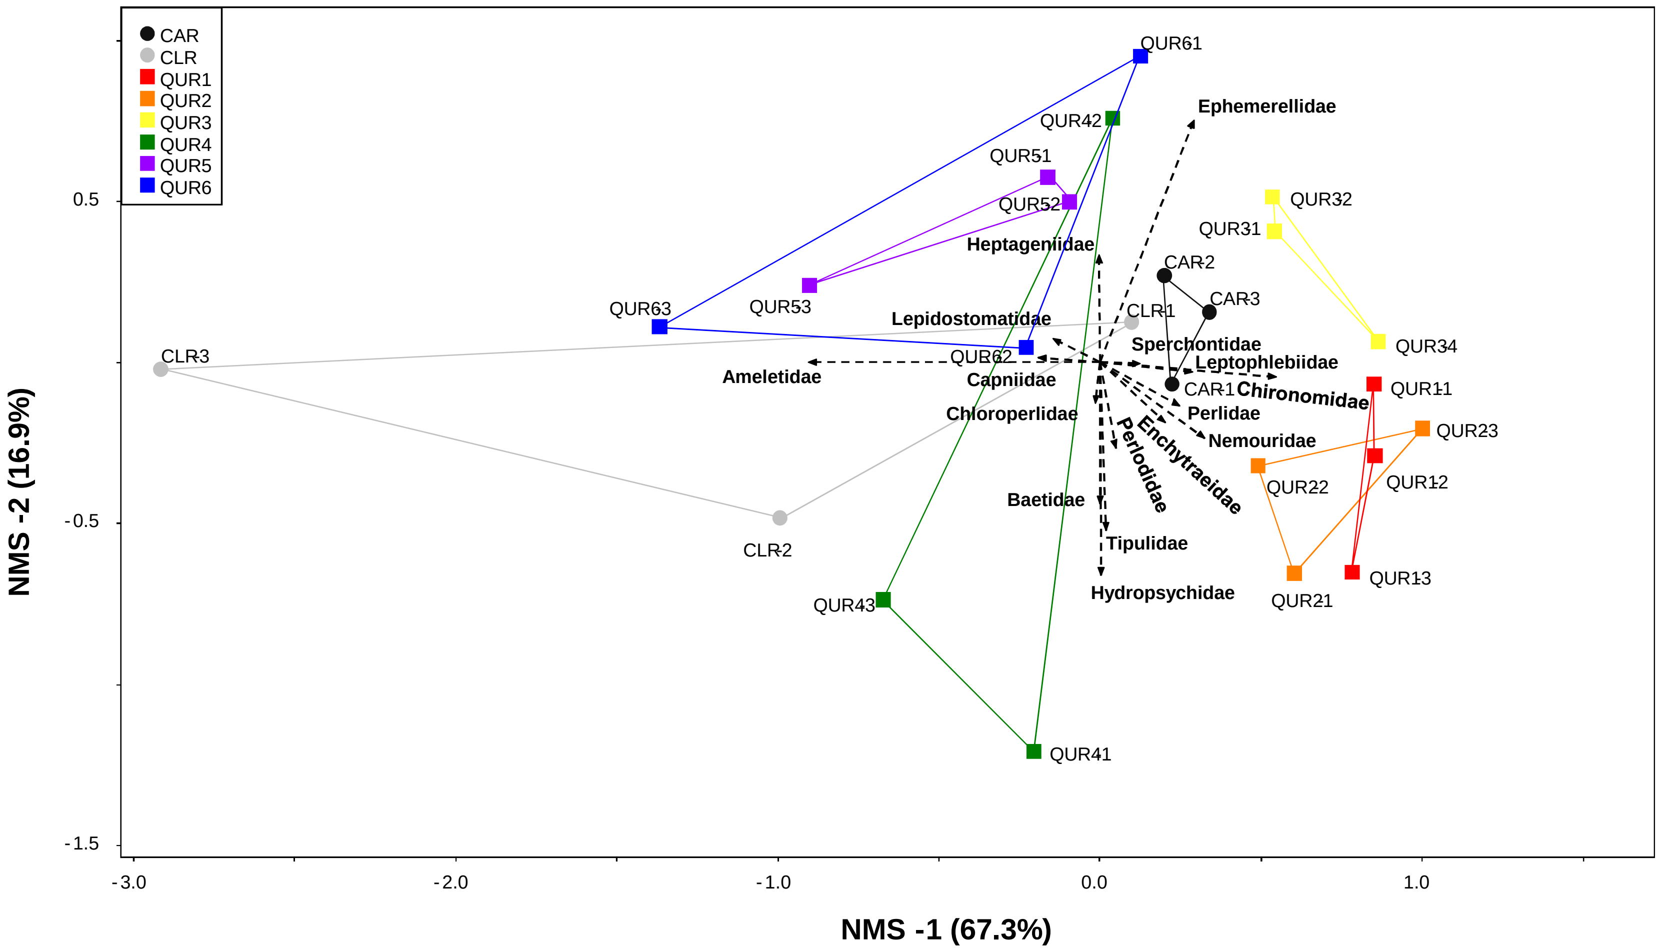

Figure 9.6: **Nonmetric multidimensional scaling biplot of benthic invertebrate community structure using two reference areas and Quesnel River areas, 3 replicates taken at each area. Family level of taxonomy employed with rare families removed if they did not occur in more than 2 of 24 samples. Displayed family vectors have significant ($p < 0.05$) Spearman's Rank Correlation with either NMS axis 1 or 2 (Appendix Table I.15), vector length is proportional to correlation strength. Convex hulls connect replicates of each area. Mount Polley Mine, October 2014.**

(Table 9.2; Figure 9.3). Taxa representing greatest positive weightings on NMS-1 included Leptophlebiidae mayflies, Perlidae and Nemouridae stoneflies, Chironomidae midges and Enchytraeidae worms (Figure 9.6), all of which were generally observed only at the Quesnel River upstream areas (i.e., QUR1, QUR2 and QUR3) and not at the downstream areas (i.e., QUR4, QUR5 and QUR6) or at either of the CAR and CLR reference areas (Appendix Tables G.30-G.31 and I.14). Ameletidae mayflies, which heavily weighted the negative scores on NMS-1 (Figure 9.6), were absent from the upstream areas (Appendix Tables G.30-G.31 and I.14). Because the taxon groups resulting in heavy positive or negative weightings on NMS-1 station scores show variable sensitivity to metals, the differences in benthic invertebrate community structure along the Quesnel River and in comparison to reference suggested by NMS-1 comparisons were not likely related to differences in metal concentrations. Rather, the indicated benthic invertebrate community differences among the Quesnel River areas and reference areas likely reflected slight differences in habitat (e.g., lakeoutlet effects, slight differences in substrate size, water velocity, etc.). The second NMS axis (NMS-2) explained 16.9% of variation in the benthic data set (Appendix Table I.13), but because no significant differences in NMS-2 station scores were indicated among the Quesnel River areas and reference areas, the NMS-2 results were not considered further.

Overall, high absolute abundance of metal-sensitive Ephemeroptera and Tanytarsini/Diamesinae midges at Quesnel River upstream areas, significantly higher relative abundance of moderately metal-sensitive Plecoptera at the Quesnel River areas compared to the CRL reference, and the general absence of significant differences in relative abundance of dominant taxon groups between Quesnel River and reference areas suggested no adverse failure-related influences to benthic dwelling invertebrates downstream of Quesnel Lake. As might be expected, there was some evidence of a lake effect, with larger proportions of filter feeding organisms (e.g., hydropsychids and Hydra; Appendix Table G.32) at the upstream areas (closer to Quesnel Lake). Rivers flowing from lakes receive lake seston (e.g., Walks and Cyr 2004) and the influence of increased seston on benthic community structure in upstream areas of such rivers has been well documented (Hoffsten 1999). These locations often also have greater periphyton biomass (Cattaneo 1996) due to factors such as flow and sediment regulation (Myers et al. 2007), seston additions (Walks and Cyr 2004), and slightly higher water temperature (Marcarelli and Wurtsbaugh 2006).

9.3 Benthic Invertebrate Tissue Quality

9.3.1 Whole Community Metals Concentration

Principal components analysis of whole community whole-body metals resulted in the first two axes explaining more variation in the original dataset than by chance alone; axes 1 and 2 explained 55.6% and 16.4% of the total extracted variance, respectively (Appendix Table I.16). Principal component axis-1 separated Quesnel River downstream areas (QUR4, QUR5 and QUR6) from upstream and reference areas along a high to low metals gradient consisting of aluminum, vanadium, iron, cobalt, cadmium, uranium, nickel, arsenic, lead, barium, chromium and titanium; Figure 9.7; Appendix Table I.17). Principal components axis-2 separated areas along a high to low gradient of copper, silver and zinc which identified Quesnel River upstream areas QUR1 and QUR2 as having elevated concentrations of these metals relative to all other areas (Figure 9.7).

Determination of which analytes had elevated concentrations in whole community benthic invertebrate tissues also involved identifying statistically significant differences among areas (Table 9.3 and Appendix Tables I.18-I.20; Appendix Figures I.13-I.15) and by comparing concentrations: 1) relative to reference area CAR; 2) within the Quesnel River upstream reach; 3) between Quesnel River upstream and downstream reaches; and 4) within the Quesnel River downstream reach. Two analytes, selenium and strontium, did not demonstrate any significant differences and patterns among areas. Consistent evidence of higher concentrations relative to CAR and decreases with distance from Quesnel Lake were observed for only three analytes that were also identified in PCA - copper, silver, and zinc (Figure 9.8). Concentrations of all other analytes demonstrated either increasing concentrations with distance or no differences. As described in Sections 5.0 to 8.0, copper was identified as the key POI and silver was identified as an IP. Zinc was not identified as either a POI or IP in Quesnel Lake sediments. The elevations of copper and silver in whole community benthic invertebrate tissues were not supported by similar elevations in other POIs and IPs and it is therefore uncertain whether they represent a failure-related influence.

9.3.2 Perlidae Metals Concentration

Principal components analysis of Perlidae whole-body metals resulted in the first two axes explaining more variation in the original dataset than by chance alone; axis-1 and -2 explained 59.9% and 23.1% of the total extracted variance, respectively (Appendix Table I.21). Principal component axis-1 separated the Quesnel River downstream areas (QUR4, QUR5 and QUR6) from the Quesnel River upstream areas and reference areas

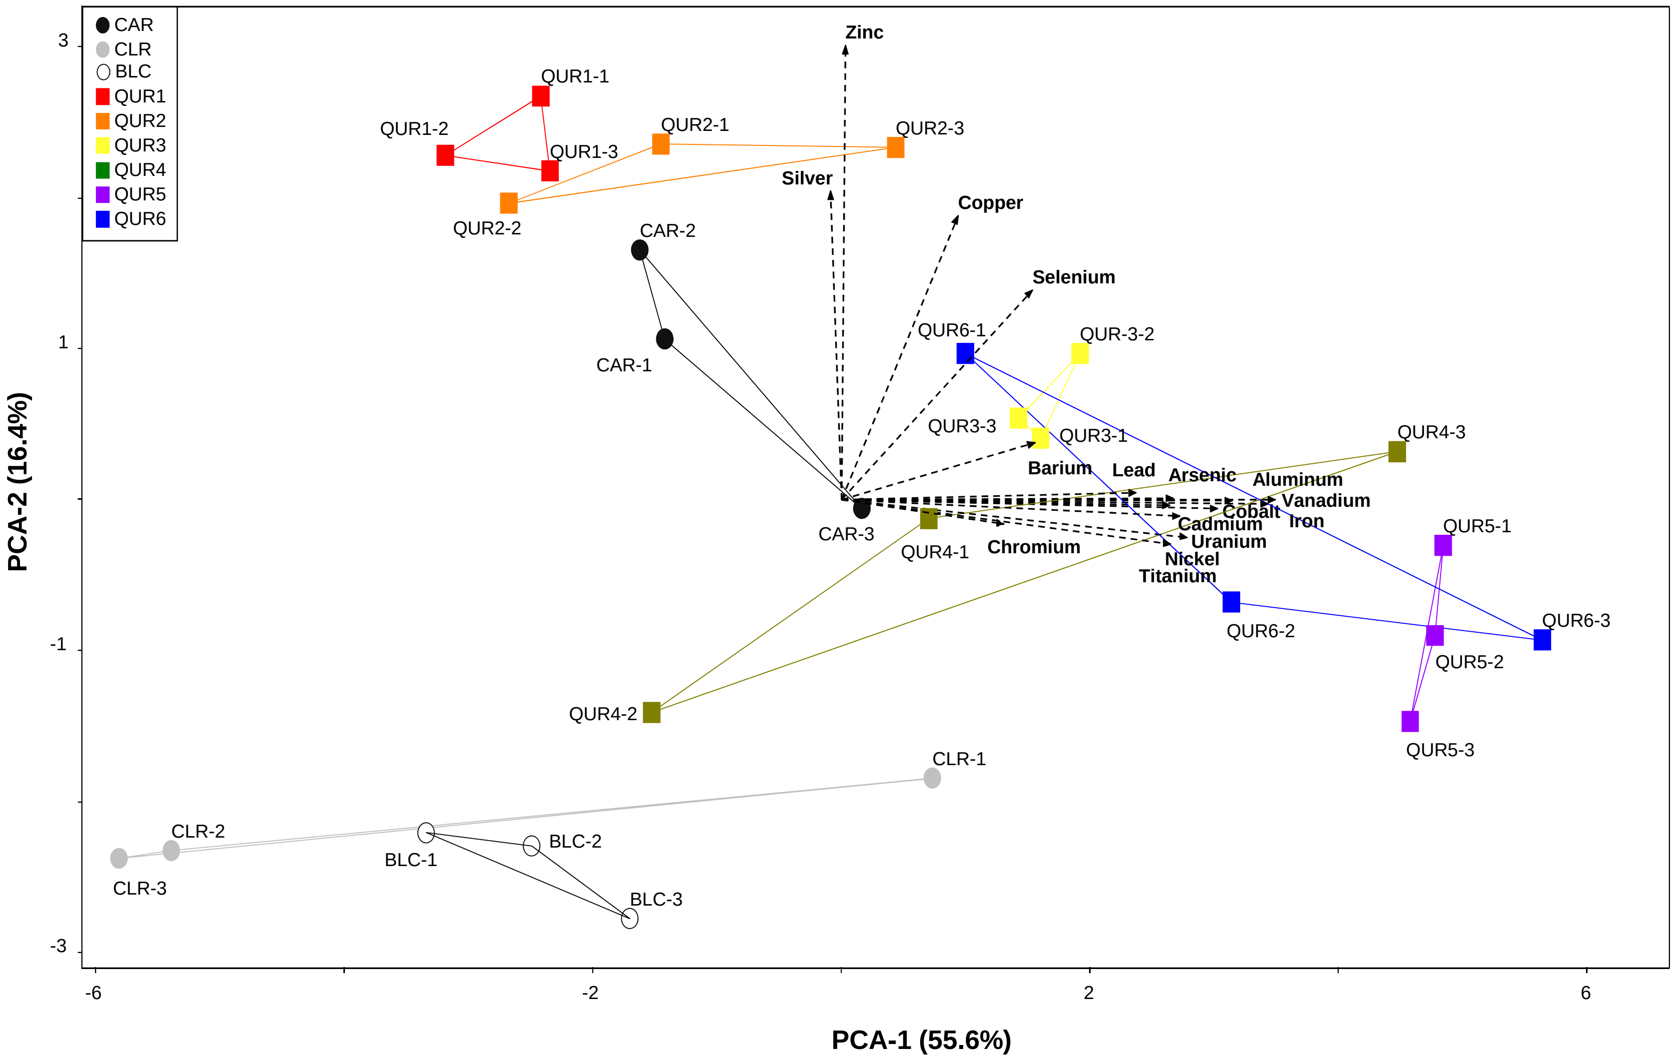

Figure 9.7: Principal Components Analysis biplot of whole benthic invertebrate community metal and metalloid tissue concentrations using three reference areas and six Quesnel River areas, 3 replicates taken at each area. Reference and Quesnel River areas area depicted by circles and squares, respectively. Displayed vectors have significant ($p < 0.05$) Spearman's Rank Correlation with either PCA axis 1 or 2 (Appendix Table I.17), vector length is proportional to correlation strength. Convex hulls connect replicates of each area. Mount Polley Mine, Quesnel River Study, October 2014.

Table 9.3: Summary of statistical assessment of whole benthic invertebrate community metal and metalloid tissue concentrations Mount Polley Mine, 2014. Magnitude of difference expressed as the number of reference standard deviations

(Shaded) Indicates a significant difference between reference and exposed area. Values indicate the magnitude of difference as the number of reference standard deviations.

[a] Reference area replicates all at MDL, therefore reference standard deviation is 0.

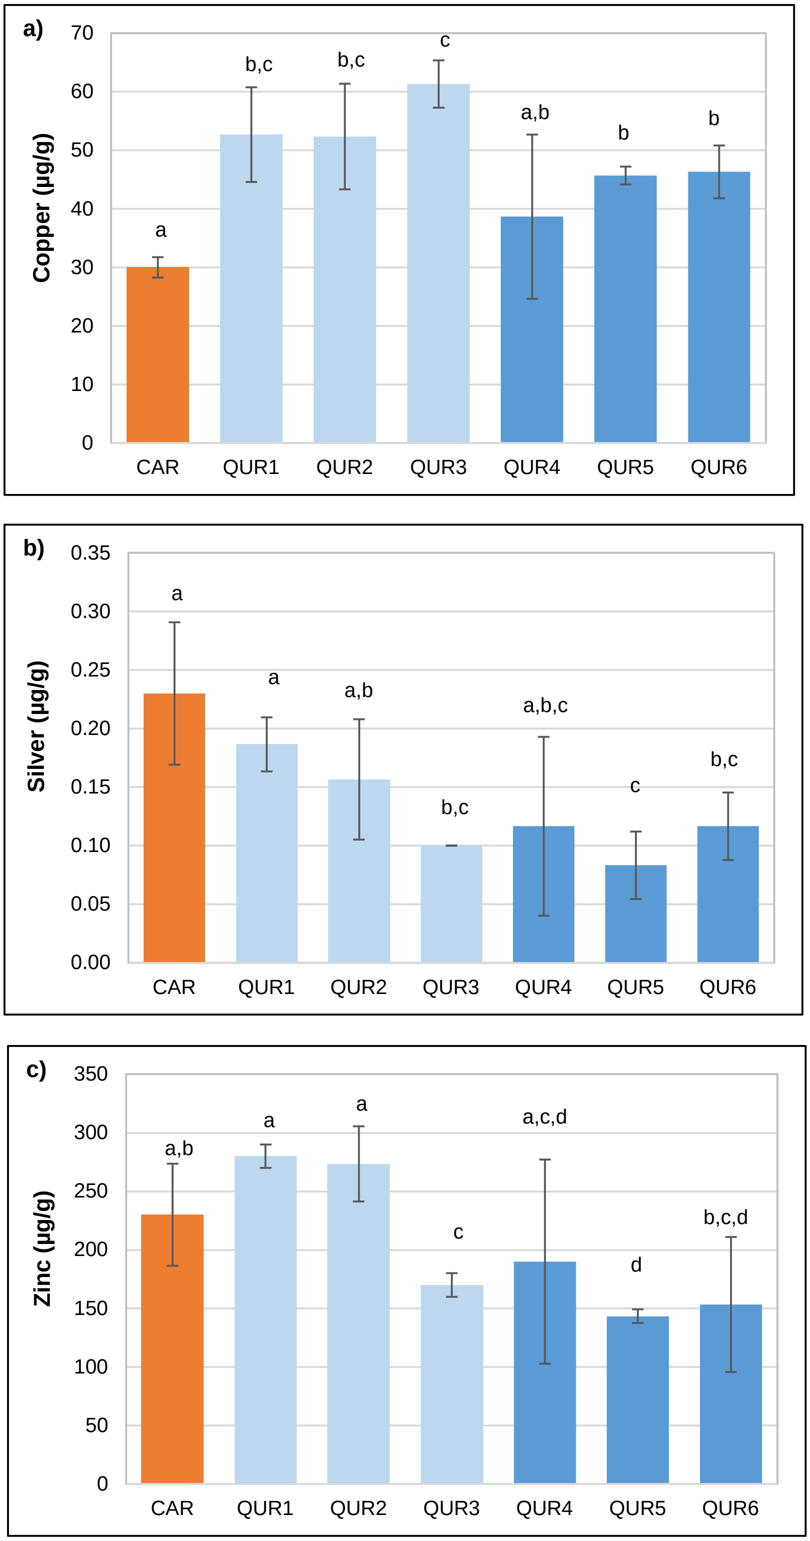

Figure 9.8: Concentrations of copper, silver and zinc in whole community benthic invertebrate tissue samples at six Quesnel River areas (blue) and one reference area CAR (orange), Mount Polley Mine, 2014.

Mean values are displayed and whiskers represent ± one standard deviation. Letters above whiskers identify statistical difference (i.e. areas that do not share a common letter are statistically different, no letter indicates non-significant ANOVA). Light and dark blue colouring represents upper and lower reaches of the Quesnel River, respectively.

along a high to low metals gradient consisting of aluminum, vanadium, iron, cobalt, uranium, nickel, arsenic, lead, barium, manganese and titanium (Figure 9.9). Principal component axis-2 separated areas along a high to low gradient of zinc, silver, selenium, cadmium and copper, which identified Quesnel River area replicate QUR6-1 as having higher concentrations of these metals and reference area BLC having lower concentrations of these metals relative to all other areas (Figure 9.9).

As with whole community tissue, determination of which analytes had elevated concentrations in Perlidae tissues involved identifying statistically significant differences among areas (Table 9.4 and Appendix Tables I.23-I.24; Appendix Figures I.16-I.17) and by comparing concentrations: 1) relative to reference area CAR; 2) within the Quesnel River upstream reach; 3) between Quesnel River upstream and downstream reaches; and 4) within the Quesnel River downstream reach. Of the metals identified in PCA, copper, selenium, silver, and zinc did not demonstrate significant differences and patterns among areas and therefore suggest no failure-related influence. Cadmium concentrations were significantly lower than the CAR reference at the two most upstream areas (QUR-1 and QUR-2) and higher downstream, also suggesting no failure-related influence.

9.4 Correlation Analysis

Correlation analysis was conducted between the benthic invertebrate community endpoints that differed among areas and 36 environmental variables. A total of 10 relationships were significant at a Bonferroni-adjusted p-level (Table 9.5). Total abundance and benthic community NMS axis-1 (Leptophlebidae mayflies, Perlidae and Nemouridae stoneflies, Chironomidae midges and Enchytraeidae worms in the positive; Ameletidae mayflies in the negative) were both positively correlated with whole community tissue metal PCA axis-2 (metals that distinguished Quesnel River upstream areas QUR1 and QUR2 including copper, selenium and silver), indicating increases in community abundance and positive NMS axis-1 values (community structure) with increasing concentrations of these metals (Table 9.5; Appendix Figure I.18). The same benthic invertebrate community endpoints were also positively correlated with periphyton thickness, indicating increased benthic abundance and relatively more of the above-noted taxa with greater periphyton thickness (indicating the benefit as a source of food and refuge). Percent Diptera (true flies) was also positively correlated with periphyton thickness (Table 9.5). The dipterans in this study are composed of the Athericidae, chironomidae, empididae, simulidae, and tipulidae; all are sessile organisms that would benefit from the refugia and food source of a thick periphyton mat.

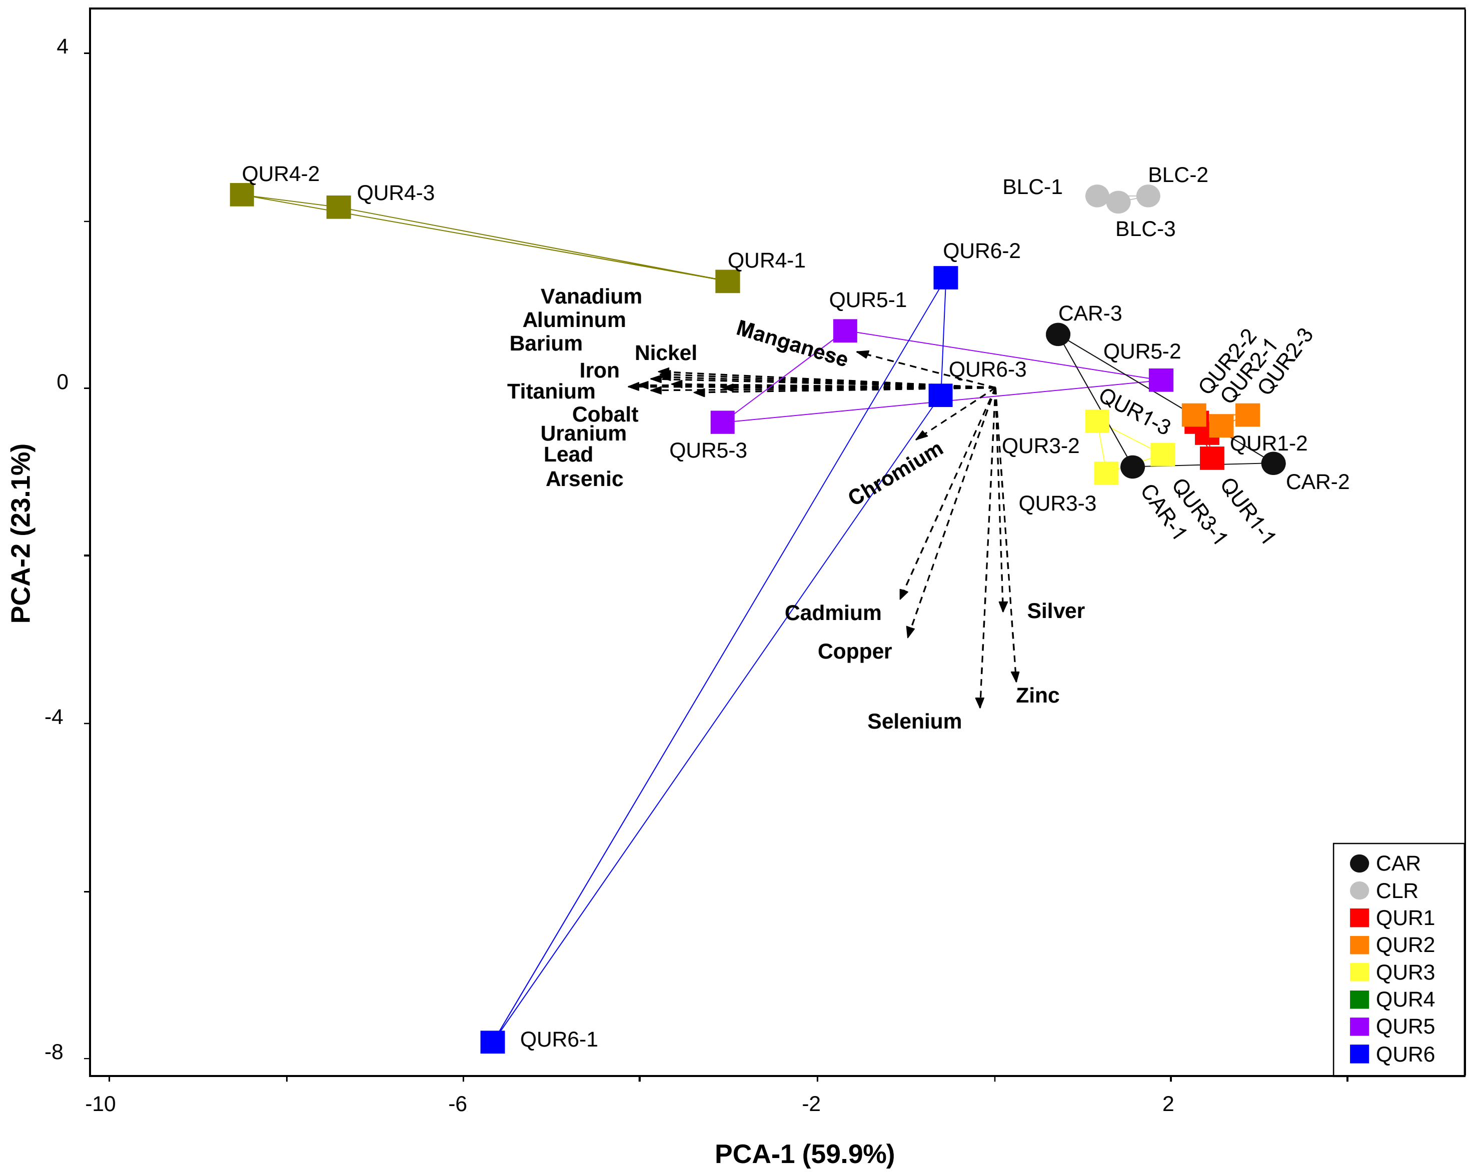

Figure 9.9: Principal Components Analysis biplot of Perlidae metal and metalloid tissue concentrations using two reference areas and six Quesnel River areas, 3 replicates taken at each area. Reference and Quesnel River areas area depicted by circles and squares, respectively. Displayed vectors have significant ($p < 0.05$) Spearman's Rank Correlation with either PCA axis 1 or 2 (Appendix Table I.22), vector length is proportional to correlation strength. Convex hulls connect replicates of each area. Mount Polley Mine, Quesnel River Study, October 2014.

Table 9.4: Summary of statistical assessment of Perlidae metal and metalloid tissue concentrations of Quesnel River areas with each reference area, Mount Polley Mine, 2014 (see Appendix I for all area comparisons). Magnitude of difference expressed as the number of reference standard deviations.

Percent Arachnida (aquatic mites) was negatively correlated with total suspended solids, total phosphorus and dissolved metals PCA-2 (calcium and strontium, which were previously identified as IPs; Table 9.5). Lastly, two additional correlations with natural variables were evident – a negative correlation between NMS axis-1 and wetted width and a positive correlation between percent Plecoptera and bankfull depth minus wetted depth (river water height compared to full-water height; Table 9.5). Overall, there was some evidence of an association between benthic invertebrate density and community composition and benthic tissue concentrations of several failure-related analytes (copper, selenium and silver), however, the strongest correlations were between the relative proportion of a number of benthic organisms and periphyton thickness.

9.5 Data Integration and Summary

Water quality data collected concurrent with benthic invertebrate community and tissue samples did not indicate an influence of the tailings dam failure on water quality of the Quesnel River. In fact, concentrations of a number of POIs identified in previous sections of this report (Sections 5.0 to 8.0), including copper, were greater in the downstream areas of the Quesnel River than in the upstream areas. Benthic invertebrate community endpoints did not demonstrate impaired conditions in the Quesnel River. Benthic invertebrate abundance was higher upstream in the Quesnel River, but appeared not to be failure-related (rather, correlation analysis suggested that it may have been due to greater periphyton cover).

Some community composition differences among areas were apparent, but there were no patterns in the spatial distribution of sensitive versus tolerant organisms that were related to proximity to Quesnel Lake. In fact, metal sensitive organisms (e.g., mayflies, Tanytarsini and Diamesinae midges) were dominant throughout the Quesnel River. Three benthic invertebrate community composition endpoints: NMS axis-1, proportion of Diptera, and proportion of Arachnida were generally higher upstream in the Quesnel River (closer to Quesnel Lake) than downstream, but correlation analysis identified that, although some relationships with POIs and IPs were evident, the most likely cause of the differences was periphyton cover. Whole community samples of benthic invertebrate tissues had higher concentrations of copper, silver, selenium, strontium, and zinc than downstream, but differences among areas were generally small. These analytes have been identified as associated with the tailings dam failure (Section 5.0 to 8.0), but poor overall concordance with the full list of POIs and IPs and the absence of a spatial gradient in concentrations of these analytes suggests no influence of the tailings dam failure. In fact, several POIs and IPs (e.g., arsenic, cobalt, iron, nickel, titanium and vanadium) were present in benthic tissue at higher concentrations downstream in the Quesnel River than upstream. Metals in Perlidae (common stoneflies) provided poorer resolution of spatial differences in metal concentrations than the whole community samples.

10.0 INTEGRATED SUMMARY

This integrated summary provides the overall findings of the Mount Polley Mining Corporation (MPMC) Sediment Quality Impact Characterization, which characterized the impact of the Mount Polley tailings dam failure (August 4th 2014) on sediment quality of Polley Lake (Area 3), Hazeltine Creek (Area 4-7) and Quesnel Lake (Area 8). The characterization included basic sediment chemistry, sediment geochemistry (partitioning and leachability), sediment toxicity testing and benthic invertebrate community condition. An evaluation of benthic invertebrate community condition and benthic invertebrate tissue quality in the Quesnel River (Area 9) assisted in identifying the spatial extent of impact. This summary is presented in two sections, the first of which (Section 10.1) provides general findings associated with the entire study area, and the second of which (Section 10.2) provides slightly more detail by area.

10.1 General Findings

The physical impact of the dam failure on sediment quality was evident within the debris field in all areas (Hazeltine Creek, Polley Lake and Quesnel Lake) based on visible differences in sediment colour and/or texture relative to reference sediments as well as in very low concentrations of total organic carbon (approximately 0.5% or less at the most impacted locations).

Sediment chemical Parameters of Interest (POIs) were identified as parameters with concentrations in impacted areas of the receiving environment that exceeded sediment quality guidelines for the protection of aquatic life (SQGs) as well as reference and/or pre-event concentrations. Importantly, concentrations of a number of metals exceeded SQGs in reference areas and/or prior to the failure (arsenic, cadmium, chromium, copper, iron, manganese, mercury, nickel and selenium), indicating locally-elevated concentrations of these metals. POIs differed somewhat by area, but consistently included arsenic, copper and iron (Table 10.1). Manganese, nickel and zinc were also identified as POIs at one area each (Table 10.1). Copper and iron were the only POIs that occurred at concentrations greater than SQG probable effect levels (PELs), which indicate concentrations with a potential to adversely affect aquatic life. Copper and iron were also identified as key contaminants of potential concern based on examination of sediment quality data collected by the BCMoE (Azimuth 2014). Of the POIs, copper was identified as elevated through all sampling areas and was typically elevated to the greatest magnitude. As such, copper concentrations also served as an effective means of characterizing the spatial extent of the influence of the failure on receiving environment

Table 10.1: Weight of evidence data integration of Sediment Quality Impact Characterization, Mount Polley Mine, 2014.

Waterbody	Area	Sediment Chemistry					Toxicity Tests [2]				Benthic Invertebrate Community [3]	Waterbody weight of evidence summary description
		Basic Chemistry			Selective Extractions (Tessier)	Shakeflask and Porewater	*Hyalella azteca*		*Chironomus dilutus*			
		Parameters of Interest (POI)	Indicator Parameters (IP)	Description [1]			Survival	Growth	Survival	Growth		
Hazeltine Creek	Upper Creek (ST16)	Arsenic Copper Iron Nickel	Calcium Cobalt Molybdenum Phosphorus Silver Sodium Titanium Vanadium	Copper, iron >PEL; Arsenic >TEL	Most POIs in residual phase; Sum of exchangeable, carbonate, and easily reducible copper >TEL	Copper > acute BCWQG Selenium > chronic BCWQG	Moderately reduced (23%)	Highly reduced (8%)	Moderately reduced (40%)	No effect	-	A clear impact on sediment quality throughout Hazeltine Creek, with all areas characterized by low sediment total organic carbon (TOC), and copper and iron concentrations > PEL and pre-event concentrations. Copper was the analyte of greatest concern. No obvious spatial patterns in POIs were observed among areas, but toxicity results confirm adverse effects associated with low TOC and elevated concentrations of POIs, including exchangeable and organic copper.
	Mid Creek (ST09)			Copper, iron >PEL; Arsenic, nickel >TEL		No exceedances of BCWQG	No effect	No effect	Slightly reduced (68%)	No effect	-	
	Lower Creek (ST02)			Copper, iron >PEL; Arsenic, nickel >TEL		Copper > acute BCWQG	No effect	No effect	Slightly reduced (62%)	No effect	-	
	Lower Creek (HAC50)			Copper, iron >PEL; Arsenic >TEL	Most POIs in residual phase; Sum of exchangeable, carbonate, and easily reducible copper >PEL	Copper > chronic and acute BCWQG	Slightly reduced (70%)	Moderately reduced (41%)	Slightly reduced (80%)	Slightly reduced (63%)	-	
Polley Lake	Mid-depth, North (POL-1)	Arsenic Copper Iron Zinc	Calcium Molybdenum Sodium Strontium Tin Titanium	Copper >PEL; Arsenic, iron >TEL	Most POIs in residual phase; Sum of exchangeable, carbonate, and easily reducible POI phases do not exceed guidelines	Copper > chronic BCWQG; manganese > acute BCWQG and reference	No effect	No effect	No effect	No effect	Moderately reduced organism density (-2.9x reference SD); Slightly reduced taxon richness (-1.3x reference SD)	A clear impact on sediment quality detectable throughout Polley Lake, but more substantial at the south end. Sediment quality was characterized by copper concentrations > PEL and pre-event concentrations, and arsenic and iron concentrations > TEL. Copper was the analyte of greatest concern, and sediment stratigraphic assessment indicated a heterogenous intrusion of mine-derived material into the lake. An unequivocal impact on benthic community was observed in the south basin as well as reduced benthic density and taxon richness observed the north basin and within mid-depth areas; however, limited toxicity suggests that effects on benthic community were more associated with low dissolved oxygen and physical change (smothering and low sediment TOC) than sediment chemistry.
	Mid-depth, South (POL-2)			Copper >PEL; Arsenic, iron >TEL		Copper > acute BCWQG and reference	No effect	No effect	Slightly reduced (74%)	No effect	Moderately reduced organism density (-2.8x reference SD); Slightly reduced taxon richness (-1.7x reference SD)	
	Deep, North (P1)			Copper >PEL; Arsenic, iron, zinc >TEL		Copper > chronic BCWQG	No effect	No effect	No effect	No effect	Moderately reduced organism density (-2.3x reference SD); Moderately reduced taxon richness (-3.9x reference SD)	
	Deep, South (P2)			Copper >PEL; Arsenic, iron >TEL	Most POIs in residual phase; Sum of exchangeable, carbonate, and easily reducible copper >TEL	Copper > acute BCWQG	No effect	No effect	No effect	No effect	No benthic invertebrates present in samples, indicating a direct impact of dam breach	
Quesnel Lake Littoral	Near-field 1 (LNF1)	Arsenic Copper Iron Manganese (Nickel) [4]	Barium Calcium Mercury Molybdenum Selenium Silver Sodium Strontium Tin Vanadium	Copper, iron >PEL; Arsenic, manganese >TEL	Most POIs in residual phase; Sum of exchangeable, carbonate, and easily reducible copper >TEL	Copper > acute BCWQG and reference	No effect	No effect	No effect	Moderately reduced (34%)	No effect on organism density; highly reduced taxon richness (-6.0x reference SD)	A clear impact on sediment quality of Quesnel Lake which appeared to be restricted to near-field littoral areas. Sediment quality characterized by copper and iron concentrations > PEL and reference in near-field areas, and increasing TOC content with distance from the mouth of Hazeltine Creek. Copper was the analyte of greatest concern, and toxicity results confirm that adverse effects were limited to the near-field areas. Reduced taxon richness in near-field areas and negative relationships between benthic metrics and metal concentrations suggest mine-related effect on benthic community, although the relative influence of physical factors (smothering, low sediment TOC) versus chemical factors is unclear.
	Near-field 2 (LNF2)			Copper, iron >PEL; Arsenic, manganese >TEL		Copper, manganese > acute BCWQG and reference	No effect	No effect	No effect	No effect	No effect on organism density; moderately reduced taxon richness (-4.2x reference SD)	
	Far-field (LFF)			Iron, nickel >TEL	Most POIs in residual phase; Sum of exchangeable, carbonate, and easily reducible POI phases do not exceed guidelines	-	No effect	No effect	No effect	No effect	No effect on organism density; slightly increased taxon richness (+1.4x reference SD)	
	Far-far-field (LFFF)			Arsenic, copper, iron, nickel >TEL		-	No effect	No effect	No effect	No effect	No effect on organism density or taxon richness	
Quesnel Lake Profundal	Near-field (PNF)	Copper (Arsenic) [4] (Iron) [4] (Manganese) [4] (Nickel) [4]	Calcium Sodium Strontium Tin Vanadium	Copper >PEL; Arsenic, iron, manganese >TEL	Most POIs in residual phase; Sum of exchangeable, carbonate, and easily reducible copper >TEL	Copper > acute BCWQG and reference	Slightly reduced (80%)	No effect	Slightly reduced (71%)	Slightly reduced (59%)	Moderately reduced organism density (-3.6x reference SD); moderately reduced taxon richness (-4.0x reference SD)	A clear impact on the sediment quality of profundal areas of Quesnel Lake that covers a substantial distance (near and far-field), with sediment quality characterized by copper concentrations > PEL in near and far-field areas, and low TOC increasing with distance from Hazeltine Creek. Copper was the analyte of greatest concern and sediment stratigraphic assessment indicated very little vertical variation in sediment chemistry. Toxicity test responses were associated with low TOC and elevated copper selective extract concentrations, and confirm that effects were limited to the near and far-field areas. Reduced benthic invertebrate density and taxon richness associated with low dissolved oxygen, low TOC and higher sediment metal concentrations suggest a mine-related effect on benthic community although the relative influence of these physical and chemical factors is unclear.
	Far-field 2 (PFF2)			Copper >PEL; Arsenic, iron, manganese >TEL		Copper > acute BCWQG and reference	No effect	Moderately reduced (47%)	Slightly reduced (81%)	No effect	Moderately reduced organism density (-3.6x reference SD); highly reduced taxon richness (-5.8x reference SD)	
	Far-field 1 (PFF1)			Copper >PEL; Arsenic, iron, nickel, manganese >TEL		Copper > acute BCWQG and reference	No effect	No effect	Slightly reduced (61%)	No effect	Moderately reduced organism density (-3.6x reference SD); moderately reduced taxon richness (-4.6x reference SD)	
	Far-far-field (PFFF)			Arsenic, iron, manganese >PEL; Copper, nickel >TEL	Most POIs in residual phase; Sum of exchangeable, carbonate, and easily reducible manganese >PEL, nickel > TEL	Manganese > acute BCWQG and reference	No effect	No effect	No effect	No effect	Moderately reduced organism density (-3.4x reference SD); moderately reduced taxon richness (-2.9x reference SD)	

[1] PEL = Probable Effect Level of the British Columbia Sediment Quality Guidelines; TEL = Threshold Effect Level of the British Columbia Sediment Quality Guidelines

[2] Significant reductions in survival and growth are classed as highly reduced (<20% of control/reference result); moderately reduced (20-50% of control/reference result), or slightly reduced (> 50% of control/reference result). Results relative to control or reference are shown in parentheses and are relative to laboratory control results for Hazeltine Creek, and relative to the highest mean normalized reference result for all other waterbodies.

[3] Magnitude of significant differences in organism density(organisms/m^2) and taxon abundance relative to reference areas classed as highly reduced (< -5 SD), moderately reduced (-5 to -2 SD), and slightly reduced (> -2 SD), where SD is the standard deviation of the reference areas. Where significant differences existed with both reference areas for a given parameter, the greatest magnitude of difference is shown.

[4] Parameters not identified as POIs in this specific waterbody / dataset, but investigated due to designation as POIs in other study waterbodies

sediment quality (Figure 10.1). Several additional parameters were identified as Indicator Parameters (IPs; parameters with concentrations below SQGs or without SQGs, but with concentrations clearly influenced by the failure; Table 10.1) and served primarily to confirm the spatial extent of the influence of the failure on receiving environment sediment quality (e.g., Figure 10.2).

Geochemical evaluations identified that concentrations of most POIs were predominantly in the residual phase, which is not considered to be mobile. Exceptions were observed with copper, manganese and molybdenum. In failure-influenced sediments, greatest concentrations of copper and molybdenum were in the “organic” phase, which likely represents mineral forms (most likely chlorite [SRK 2015]; also not considered to be mobile). In several mine-influenced areas, concentrations of copper in exchangeable, carbonate and easily reducible forms were greater than reference, but separate geochemical evaluation (SRK 2015) concluded that copper mobility was limited. Partitioning of manganese also differed from most POIs. Manganese was in the residual form in most areas except for reference areas where it was in an easily reducible form, possibly representing surface enriched manganese oxides. These geochemical findings indicate that, although concentrations of several metals in sediment exceed provincial guidelines, copper and other associated metals may not be harmful to aquatic life.

Vertical patterns of sediment chemistry and sediment porewater chemistry in cores collected from areas of Polley and Quesnel lakes within the debris field indicated that sediments were generally oxidizing with the exception of interface areas (areas where event derived-materials touch native materials). In Polley Lake, there was evidence of heterogeneous intrusion of event-derived material; whereas in Quesnel Lake deep areas, sediment was vertically uniform and consistent with settling rather than intrusion. Some reduction-driven dissolution of iron oxides was evident in Polley Lake (but not Quesnel Lake), possibly due to greater heterogeneity in association with apparent intrusion. Although sediment diagenesis (chemical ageing) is a long-term process, early findings indicated that sediments were predominantly oxidizing, which suggests limited mobility of sediment-associated metals. This is consistent with separate evaluation of potential post-depositional mobility, which indicated very low risk of metal mobilization (SRK 2015).

Sediment toxicity testing indicated effects to both test organisms (the amphipod *Hyalella azteca* and the midge *Chironomus dilutus*) in Hazeltine Creek, Quesnel Lake near-field littoral areas and Quesnel Lake near-field and far-field profundal areas, as well as limited effects in Polley Lake, the Quesnel Lake littoral far-field and far-far-field areas and the Quesnel Lake profundal far-far-field area (Table 10.1). However, responses of the toxicity

test organisms were generally quite modest (e.g., the lowest survival in Quesnel Lake beyond near-field areas was 84% for *H. azteca* and 58% for *C. dilutus*). Correlation analyses indicated some consistent relationships between survival or growth of toxicity test organisms and sediment physical and chemical variables. Specifically, there were consistent positive relationships between biological responses (survival and growth) and sediment total organic carbon, and consistent negative relationships between biological responses and concentrations of POIs and IPs, including selective copper extracts. This suggests an effect on test organism survival and growth associated with some combination of low TOC (i.e., inorganic failure-impacted sediments) and elevated POI concentrations, both of which are failure-related. The relative influence of the potential causes (low TOC and elevated POI concentrations) could not be resolved with the available data.

Benthic invertebrate community assessment indicated effects to benthic invertebrates in a number of areas, ranging from an absence of organisms (Polley Lake south basin and several stations at a far-field area in the Quesnel Lake profundal zone) to lower density and taxon richness (Hazeltine Creek, Polley Lake, Quesnel Lake littoral near-field areas, Quesnel Lake near- and far-field areas) to limited differences in community composition (Quesnel Lake littoral far- and far-far-field areas, Quesnel Lake profundal far-far-field area; Table 10.1). There were no failure-related effects to the Quesnel River benthic invertebrate community or tissue chemistry, suggesting that the spatial extent of effects associated with the dam failure lies within Quesnel Lake. Correlation analyses indicated some consistent relationships between benthic invertebrate community metrics and supporting habitat measures, sediment physical variables and chemical variables. Specifically, as also observed for the sediment toxicity data, there were consistent positive relationships between biological responses and sediment total organic carbon, and consistent negative relationships between biological responses and concentrations of POIs and IPs, including selective copper extracts. These relationships corroborate the findings of toxicity testing and suggest an effect associated with some combination of physical impact (e.g., smothering or unsuitable substrate condition), low TOC (i.e., inorganic failure-impacted sediments) and elevated POI concentrations. In Polley Lake and in Quesnel Lake deep areas, there were also consistent positive relationships with dissolved oxygen content and negative relationships with specific conductance. The relative influence of the potential causes (physical impact, low TOC, elevated POI concentrations/specific conductance and lower dissolved oxygen [deep areas only]) could not be resolved with the available data.

Overall, the MPMC tailings dam failure had a physical and chemical impact on sediment quality within the debris field in Polley Lake, Hazeltine Creek and Quesnel Lake, the former evident visually and in low TOC content and the latter most evident in elevated copper and iron, but also evident in moderately elevated concentrations of arsenic, manganese, nickel and zinc. Geochemical evaluation consistently indicated that most metals were predominantly in the residual form (associated with mineral matrices and not considered to be mobile or biologically available). Copper was a key exception, with most copper present in the “organic” phase which likely represents mineral forms and concentrations of copper in exchangeable, carbonate and easily reducible forms greater at impacted areas than reference. Separate geochemical evaluation (SRK 2015) indicated limited copper mobility. Sediment toxicity and benthic invertebrate community condition both indicated some failure-related effects. Responses, although often small in magnitude (even associated with samples representing the worst conditions such as those in Hazeltine Creek; Table 10.1), were evident in Hazeltine Creek as well as areas further from the sources but within the debris field (i.e., near-field areas of Polley and Quesnel littoral; near-field and far-field areas of Quesnel profundal). Examination of relationships between biological responses and sediment physical/chemical condition suggested that observed responses were related to physical disturbance, low TOC (i.e., inorganic failure-impacted sediments) and elevated POI concentrations. In deep areas of lakes, responses were also related to lower dissolved oxygen and higher specific conductance. The relative influence of the potential causes (physical disturbance, low TOC, low dissolved oxygen in deep lake areas, and elevated POI concentrations and specific conductance) could not be resolved with the available data. Evaluation of the spatial extent of the sediment quality impact indicated that the spatial extent remains within Quesnel Lake and is largest in the profundal zone (approximately 7.5 kilometers longitudinally).

The sediment quality impact characterization was designed and implemented as an initial response. There are a few remaining uncertainties, the most important of which are the relative influence of physical impact (e.g., smothering or unsuitable substrate condition), low total organic content, low dissolved oxygen (deep lakes area only) and elevated POI concentrations on sediment-associated biota, and the post-depositional chemical stability of newly deposited sediment in Polley and Quesnel lakes. In addition to focused monitoring of recovery, these uncertainties should be addressed.

10.2 Area-Specific Findings

Hazeltine Creek

The MPMC dam failure had an impact on sediment quality throughout Hazeltine Creek. Sediment collected from Hazeltine Creek following the dam failure had low TOC content (< 0.2%) and concentrations of copper and iron that were greater than SQG PELs and pre-event concentrations. Concentrations of arsenic and nickel were greater than SQG TELs at a subset of sample locations and only in <63 µm sediment (not <2.0 mm sediment). Copper was more substantially elevated than any other analyte, with mean concentrations up to five times the PEL and 15 times pre-event concentrations. Sediment geochemical evaluations indicated that, for most POIs and IPs, concentrations were mostly in the residual phase, a fraction that is not considered mobile or biologically available. However, calcium and copper were notable exceptions, with the majority calcium occurring in the carbonate phase and the majority of copper occurring in the "organic" phase, which likely represents mineral forms (most likely chlorite [SRK 2015]; also not considered to be mobile). Copper was also present in exchangeable, carbonate and easily reducible forms, but separate geochemical evaluation (SRK 2015) indicated limited mobility.

Sediment toxicity testing indicated some adverse effects to both test species (*H. azteca* and *C. dilutus*), but also indicated no effect at some combinations of endpoint (survival and growth) and location (e.g., no reduction in *H. azteca* survival and growth at the mid-stream area and no reduction in *C. dilutus* growth at three of four areas). Survival and growth of *C. dilutus* were weakly associated with concentrations of several POIs and IPs. Survival of *H. azteca* was positively correlated with percent fines and calcium, and growth of *H. azteca* was weakly associated percent fines and percent TOC in the positive direction, and with POIs and IPs (including exchangeable and organic copper) in the negative direction. These relationships suggest biological effects due to low TOC and elevated concentrations of failure-related metals.

Polley Lake

The MPMC dam failure had an impact on sediment quality of Polley Lake, most pronounced at the deepest sampling location on the south side of Polley Lake (nearest to the point of tailings dam failure). Sediment collected from Polley Lake following the dam failure was characterized by concentrations of copper greater than SQG PELs and pre-event concentrations, and concentrations of arsenic, iron, and zinc greater than TELs and pre-event concentrations. Copper concentrations at mid-depth areas were similar to pre-event concentrations, but concentrations in the deeper basins were higher than PELs and pre-event concentrations (approximately 3.6- and 2.4-times, respectively). Sediment geochemical evaluations indicated that, for most POIs and IPs, concentrations were mostly in the residual phase, a fraction that is not considered mobile. However, copper and molybdenum were notable exceptions, with the majority occurring in the “organic” phase, which likely represents mineral forms (most likely chlorite [SRK 2015]; also not considered to be mobile). Copper was also present in exchangeable, carbonate and easily reducible forms at concentrations greater than reference, but separate geochemical evaluation (SRK 2015) indicated limited mobility.

Sediment stratigraphy evaluation indicated that copper was elevated at the south basin at a depth of 6 to 10 cm below surface, indicating heterogeneous intrusion rather than surface influence (settling). Pore-water evaluation indicated some locally elevated metal concentrations at interfaces of mine-derived materials and native sediment. Failure-affected sediments were generally oxidizing, with sediment becoming more reducing with depth (sub-oxic but not sulphidic). Sediments were likely sufficiently reducing to drive reductive dissolution of iron oxides, but because mine-derived material is mostly mineral, this may not result in significant metal mobilization. Separate evaluation of potential post-depositional mobility indicated very low risk of metal mobilization (SRK 2015).

Sediment toxicity testing indicated no adverse effect to *H. azteca*, reduced survival of *C. dilutus* at one location (73% relative to the concurrent laboratory control at the south basin of Polley Lake; Station P2), and no effect on growth of *C. dilutus*. The benthic invertebrate community of Polley Lake had lower density and taxon richness than the reference lake (Bootjack Lake). Density and taxon richness were within the range documented in some baseline studies, but below those documented in 1999 (the only pre-event sampling with full taxonomic data available). There were no benthic organisms at the south basin of Polley Lake, indicating an impact. Benthic invertebrate community composition at the Polley Lake north basin differed dramatically from 1999, with greater proportional representation of oligochaetes and lower proportional representation of Chironomidae, whereas a similar difference was not observed at reference. As oligochaetes are pollution tolerant organisms, this suggests an impact to benthic invertebrate community composition.

Correlation analysis indicated few significant relationships between the toxicity tests results and sediment physical/chemical conditions, which is consistent with a limited biological response. Correlation analysis indicated significant relationships between several benthic invertebrate community endpoints and dissolved oxygen, specific conductance, sediment TOC content and sediment POI and IP concentrations – in general, there were indications that benthic invertebrate density and taxon richness decreased and Bray-Curtis index of dissimilarity increased with lower dissolved oxygen, lower TOC content and higher specific conductance and POI/IP concentrations, which suggests a potential failure-related effect on these metrics. A number of supporting benthic invertebrate community metrics (e.g., percent oligochaete worms and CA axes) showed similar relationships. Given the limited toxicity, the observed effects on the benthic invertebrate community were more likely due to low dissolved oxygen and physical factors (i.e., smothering and low TOC) than sediment chemistry.

Quesnel Littoral

The MPMC dam failure had an impact on sediment quality in the Quesnel Lake littoral zone, but it was spatially limited to the near-field areas (located in the debris field within approximately 1 km of the mouth of Hazeltine Creek). Sediment collected from littoral areas of Quesnel Lake following the dam failure was characterized by increasing TOC with distance from Hazeltine Creek, near-field concentrations of copper and iron greater than SQG PELs and reference concentrations, and near-field concentrations of arsenic and manganese greater than TELs and reference but lower than pre-event concentrations recorded in Hazeltine Creek. Sediment geochemical evaluations indicated that, for most POIs and IPs, concentrations were mostly in the residual phase, a fraction that is not considered mobile or biologically available. However, copper and molybdenum were notable exceptions, with the majority occurring in the “organic” phase, which likely represents mineral forms (most likely chlorite [SRK 2015]; also not considered to be mobile). Copper was also present in exchangeable, carbonate and easily reducible forms at concentrations greater than reference, but separate geochemical evaluation (SRK 2015) indicated limited mobility.

Sediment toxicity testing indicated no adverse effects to *H. azteca* and *C. dilutus* at near-field area 2, the far-field area and the far-far-field area, but sediments collected at near-field area 1 caused reduced survival and growth of *C. dilutus*. Benthic invertebrate community assessment indicated that the benthic invertebrate community of the Quesnel Lake littoral near-field areas (near-field area 1 and near-field area 2) had lower taxon richness than both reference areas. Nonetheless, community composition, although variable among areas, was not significantly different at the exposed areas relative to both references.

Correlation analysis indicated negative relationships between survival and growth of *H. azteca* and easily reducible copper and a negative relationship between survival of *C.*

dilutus and carbonate copper. Positive relationships to sediment TOC content were apparent for the same toxicity test endpoints. Correlation analysis also indicated a number of significant relationships between benthic invertebrate community metrics and sediment metal concentrations (including selective copper extracts) that suggest potential failure-related effects to density, taxon richness and community structure associated with low TOC and elevated concentrations of tailings dam failure-associated POIs and IPs. As the positive influence of TOC cannot be separated from potential negative effects due to elevated metal concentrations, it is uncertain whether the effects were physical (i.e., due to smothering or low TOC) or chemical.

Quesnel Profundal

The MPMC dam failure had an impact on sediment quality in the Quesnel Lake profundal zone that extends through the far-field areas and covers a substantial linear distance (on the order of 7.5 km longitudinally; see Figures 10.1 and 10.2). As also observed in the Quesnel Lake littoral areas, sediment total organic carbon content was low in exposed areas and increased to concentrations similar to reference with distance from the mouth of Hazeltine Creek. Sediment collected from exposed profundal areas of Quesnel Lake following the dam failure was characterized by concentrations of copper greater than the SQG PEL and reference concentrations, and by concentrations of a number of IPs (calcium, sodium, strontium and tin) that decreased with distance from the mouth of Hazeltine Creek. A number of additional metals were elevated to concentrations greater than SQG TELs and reference at the far-far-field area only (arsenic, cadmium, chromium, manganese and nickel), which suggests that their elevations were not failure-related. Sediment geochemical evaluations indicated that, for most POIs (including those identified on the basis of sediment quality data from Hazeltine Creek, Polley Lake and the Quesnel Lake littoral zone) and IPs, concentrations were mostly in the residual phase, a fraction that is not considered mobile or biologically available. However, copper and manganese were notable exceptions. The majority of copper occurred in the “organic” phase, which likely represents mineral forms (most likely chlorite [SRK 2015]; also not considered to be mobile). The majority of manganese at mine-influenced areas was in the residual form, but at reference areas was in easily reducible form, possibly representing surface enriched manganese oxides at reference areas. Copper was also present in exchangeable, carbonate and easily reducible forms at concentrations greater than reference, but separate geochemical evaluation (SRK 2015) indicated limited mobility.

Sediment stratigraphy evaluation indicated little vertical variation in sediment chemistry at a location within the debris field; only slightly higher concentrations of a number of failure-related metals in surficial sediments, possibly due to higher concentrations associated with the very fine particles that were last to settle out of the water column. Sediment and pore-water analysis indicated that sediments were under oxidizing conditions (there was no evidence of reducing conditions), and therefore, metals are likely to remain associated with particulates. Porewater metal concentrations did not mirror sediment concentrations and were relatively elevated at 3 to 7 cm sub-surface. Sediments were not fully compacted when the cores for sediment and pore-water chemistry were collected. Separate evaluation of potential post-depositional mobility indicated very low risk of metal mobilization (SRK 2015).

Sediment toxicity testing indicated an apparent effect on survival of *H. azteca* and on survival and growth of *C. dilutus* at the near-field area. Reduced growth of *H. azteca* was observed at the upstream far-field area (highlighted primarily due to a high growth rate in one laboratory control), and reduced survival (but not growth) of *C. dilutus* was observed at both far-field areas. Benthic invertebrate community assessment indicated that the benthic invertebrate community of the Quesnel Lake profundal zone (including reference areas) was composed of few organisms. The upstream far-field area was most substantially impacted; with no organisms present at four of five stations. Density of the near-field and far-field areas was particularly low (<50 organisms/m^2), and the upstream far-field area had significantly lower taxon richness than both reference areas. Community composition at the near-field and far-field areas differed significantly from both references; however, compositional differences between reference areas were as large as those between exposed and reference areas.

Correlation analysis indicated some positive relationships between biological endpoints (survival and growth of the toxicity test organisms and benthic invertebrate community endpoints) and dissolved oxygen (benthic community only) and sediment total organic carbon content, as well as negative relationships between the biological endpoints and specific conductance (benthic invertebrate community only) and concentrations of a number of POIs and IPs in sediment. The positive influence of dissolved oxygen and sediment TOC cannot be separated from potential negative effects due to elevated sediment metal concentrations (including copper in selective extracts), and it is therefore uncertain whether the effects were associated with dissolved oxygen, physical factors (i.e., due to smothering or low TOC) or sediment chemistry.

Quesnel River

Water quality data collected in the Quesnel River concurrent with benthic invertebrate community and tissue sampling did not indicate an influence of the tailings dam failure on water quality of the Quesnel River, which is consistent with the findings of a comprehensive evaluation of the impact of the tailings dam failure of receiving water quality (Golder 2015). In fact, concentrations of a number of POIs identified in Hazeltine Creek, Polley Lake and Quesnel Lake, were greater at the downstream areas of the Quesnel River than at the upstream areas (i.e., farther away from the mine).

Benthic invertebrate community endpoints did not indicate impaired conditions in the Quesnel River. Benthic invertebrate abundance was higher upstream in the Quesnel Rive than downstream, but appeared not to be failure-related, as correlation analysis suggested that it may have been due to greater periphyton cover. Some community composition differences among areas in the Quesnel River and reference rivers were apparent, but there were no patterns in the spatial distribution of sensitive versus tolerant organisms that were related to proximity to Quesnel Lake. In fact, metal sensitive organisms (e.g., mayflies, Tanytarsini and Diamesinae midges) were dominant throughout the Quesnel River. Three benthic invertebrate community composition endpoints: an ordination axis (non-metric multidimensional scaling axis-1), proportion of Diptera, and proportion of Arachnida were generally higher upstream in the Quesnel River (closer to Quesnel Lake) than downstream. Correlation analysis identified that, although some relationships with POIs and IPs were evident, the most likely cause of the differences was periphyton cover.

Whole benthic invertebrate community tissue samples had higher concentrations of copper, silver, selenium, strontium, and zinc upstream than downstream, but differences among areas were generally small. These analytes have been identified as associated with the tailings dam failure, but poor overall concordance with the full list of POIs and IPs and the absence of a spatial gradient in concentrations of these analytes in water suggests they may not be related to the tailings dam failure. In fact, several POIs and IPs (e.g., arsenic, cobalt, iron, nickel, titanium and vanadium) were present in benthic invertebrate tissue at higher concentrations downstream in the Quesnel River than upstream. Overall, this evaluation suggests that the spatial extent of biological impact associated with the MPMC dam failure did not extend to the Quesnel River.

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.

[2] Concentrations reported in 1995 and 1996 were for the silt and clay (<63 µm) fraction only.

[3] Some unusually high sediment metal concentrations were reported for 1996 (HKP 1997) and are suspected errors.

[4] Particle fractions for these samples are as follow: gravel (>2mm), sand (2.0mm - 0.050mm), silt (0.050mm - 0.002mm), clay (<0.002mm).

[5] Summary statistics exclude data from 1996 (HKP 1997) due to suspected errors with this data.

(Shaded) Method detection limit (MDL) was > maximum reported detectable value (excluding 1996 data); value was omitted from calculation of summary statistics.

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is repc

[2] Concentrations reported in 1995 and 1996 were for the silt and clay (<63 µm) fraction only.

[3] Some unusually high sediment metal concentrations were reported for 1996 (HKP 1997) and are suspected errors.

[4] Particle fractions for these samples are as follow: gravel (>2mm), sand (2.0mm - 0.050mm), silt (0.050mm - 0.002mm), clay (<0.002mm).

[5] Summary statistics exclude data from 1996 (HKP 1997) due to suspected errors with this data.

[shaded cell] Method detection limit (MDL) was > maximum reported detectable value (excluding 1996 data); value was omitted from calculation of summary statistics.

Table A.1: Raw sediment quality data for upper Hazeltine Creek, 1995-2013 [1].

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.

[2] Concentrations reported in 1995 and 1996 were for the silt and clay (<63 µm) fraction only.

[3] Some unusually high sediment metal concentrations were reported for 1996 (HKP 1997) and are suspected errors.

[4] Particle fractions for these samples are as follow: gravel (>2mm), sand (2.0mm - 0.050mm), silt (0.050mm - 0.002mm), clay (<0.002mm).

[5] Summary statistics exclude data from 1996 (HKP 1997) due to suspected errors with this data.

Method detection limit (MDL) was > maximum reported detectable value (excluding 1996 data); value was omitted from calculation of summary statistics.

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.

[2] concentrations reported in 1995 and 1996 were for the silt and clay (<63 µm) fraction only.

[3] some unusually high sediment metal concentrations were reported for 1996 (HKP 1997) and are suspected errors.

[4] Particle fractions for these samples are as follow: gravel (>2mm), sand (2.0mm - 0.050mm), silt (0.050mm - 0.002mm), clay (<0.002mm).

[5] Summary statistics exclude data from 1996 (HKP 1997) due to suspected errors with this data.

(grey shading) Method detection limit (MDL) was > maximum reported detectable value (excluding 1996 data); value was omitted from calculation of summary statistics.

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.
[2] Station L assessed in 1989 is equivalent to station P2 assessed in following sampling years. Concentrations reported in 1989 were for the <0.149mm fraction only.
[3] Concentrations reported in October 1996 were for the silt and clay (<63µm) fraction only.
[4] Summary statistics for mid-depth areas include data from stations B (1989), PL-1 to PL-5 (May 2009), A to C (October 2009), and POL-1 to POL-5 (2012).
[a] Particle size fractions for these samples are as follows: sand (0.053mm-2.0mm), silt (0.002mm-0.053mm), clay (<0.002mm).
[b] Particle size results for this station are based on one composite sample and the size fractions are as follows: sand (2.0mm - 0.0705mm), silt (0.0705mm - 0.0041mm), clay (<0.0041mm).
[c] Particle size results for this station are based on one composite sample,and the size fractions are as follows: sand (2.0mm - 0.0675mm), silt (0.0675mm - 0.0041mm), clay (<0.0041mm)
[d] Particle size fractions for these samples are as follows: sand (2.0mm - 0.063mm), silt (0.063mm - 0.0040mm or 0.0039mm), clay (<0.0040mm or 0.0039mm)
[e] Reported sand fraction also included silt and clay fractions (< 0.002mm - 2mm).
(grey shading) Method detection limit (MDL) was > maximum detectable value for basin or mid-depth data sets; value was omitted from calculation of respective summary statistics.

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.

[2] Station L assessed in 1989 is equivalent to station P2 assessed in following sampling years. Concentrations reported in 1989 were for the <0.149mm fraction only.

[3] Concentrations reported in October 1996 were for the silt and clay (<63µm) fraction only.

[4] Summary statistics for mid-depth areas include data from stations B (1989), PL-1 to PL-5 (May 2009), A to C (October 2009), and POL-1 to POL-5 (2012).

[a] Particle size fractions for these samples are as follows: sand (0.053mm-2.0mm), silt (0.002mm-0.053mm), clay (<0.002mm).

[b] Particle size results for this station are based on one composite sample and the size fractions are as follows: sand (2.0mm - 0.0705mm), silt (0.0705mm - 0.0041mm), clay (<0.0041mm).

[c] Particle size results for this station are based on one composite sample,and the size fractions are as follows: sand (2.0mm - 0.0675mm), silt (0.0675mm - 0.0041mm), clay (<0.0041mm)

[d] Particle size fractions for these samples are as follows: sand (2.0mm - 0.063mm), silt (0.063mm - 0.0040mm or 0.0039mm), clay (<0.0040mm or 0.0039mm)

[e] Reported sand fraction also included silt and clay fractions (< 0.002mm - 2mm).

(Grey shading) Method detection limit (MDL) was > maximum detectable value for basin or mid-depth data sets; value was omitted from calculation of respective summary statistics.

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.

[2] Stations LN and LS assessed in 1989 are approximately equivalent to stations B1 and B2 assessed in following sampling years. Concentrations reported in 1989 were for the <0.149mm fraction only.

[3] Concentrations reported in October 1996 were for the silt and clay (<63µm) fraction only.

[4] Summary statistics for mid-depth areas include data from stations B2 and B3 (1989), A (2009), and BOL-1 to BOL-5 (2012). Where all values were < MDL, the 95th percentile is shown as the maximum MDL.

[a] Particle size fractions for these samples are as follows: sand (2.0mm - 0.053mm), silt (0.053mm - 0.002mm), clay (<0.002mm).

[b] Particle size results for this station are based on one composite sample and the size fractions are as follows: sand (2.0mm - 0.065mm), (0.065mm - 0.0041mm), clay (<0.0041mm).

[c] Particle size fractions for these samples are as follows: sand (2.0mm - 0.063mm), silt (0.063mm-0.0039 or 0.0038mm), clay (<0.0039 or < 0.0038mm).

[d] Reported sand fraction also included silt and clay fractions (< 0.002mm - 2.0mm).

(shaded cell) Method detection limit (MDL) was > maximum detectable value for basin or mid-depth data sets; value was omitted from calculation of respective summary statistics.

Table A.4: Raw sediment quality data for Bootjack Lake, 1989 - 2012 [1].

[1] All values reported as < method detection limit (MDL) were used at the MDL value for calculation of summary statistics. If all reported values were < MDL, the mean is reported as < MDL.

[2] Stations LN and LS assessed in 1989 are approximately equivalent to stations B1 and B2 assessed in following sampling years. Concentrations reported in 1989 were for the <0.149mm fraction only.

[3] Concentrations reported in October 1996 were for the silt and clay (<63µm) fraction only.

[4] Summary statistics for mid-depth areas include data from stations B2 and B3 (1989), A (2009), and BOL-1 to BOL-5 (2012). Where all values were < MDL, the 95th percentile is shown as the maximum MDL.

[a] Particle size fractions for these samples are as follows: sand (2.0mm - 0.053mm), silt (0.053mm - 0.002mm), clay (<0.002mm).

[b] Particle size results for this station are based on one composite sample and the size fractions are as follows: sand (2.0mm - 0.065mm), (0.065mm - 0.0041mm), clay (<0.0041mm).

[c] Particle size fractions for these samples are as follows: sand (2.0mm - 0.063mm), silt (0.063mm-0.0039 or 0.0038mm), clay (<0.0039 or < 0.0038mm).

[d] Reported sand fraction also included silt and clay fractions (< 0.002mm - 2.0mm).

(Shaded cell) Method detection limit (MDL) was > maximum detectable value for basin or mid-depth data sets; value was omitted from calculation of respective summary statistics.

APPENDIX C

DATA QUALITY ASSESSMENT

APPENDIX C: DATA QUALITY ASSESSMENT

LIST OF TABLES

After Page…

C1.0 INTRODUCTION

Data Quality Assessment (DQA) was conducted on data collected as part of the Mount Polley Mining Corporation Sediment Quality Impact Characterization (SQIC). The objective of DQA is to define the overall quality of the data presented in the report, and, by extension, the confidence with which the data can be used to derive conclusions.

C1.1 Background

A variety of factors can influence the physical, chemical and biological measurements made in an environmental study and thus affect the accuracy and/or precision of the data. Inconsistencies in sampling or laboratory methods, use of instruments that are inadequately calibrated or which cannot measure to the desired level of accuracy or precision, and contamination of samples in the field or laboratory are just some of the potential factors that can lead to the reporting of data that do not accurately reflect actual environmental conditions. Depending on the magnitude of the problem, inaccuracy or imprecision have the potential to affect the reliability of any conclusions made from the data. Therefore, it is important to ensure that programs incorporate appropriate steps to control the non-natural sources of data variability (i.e., minimize the variability that does not reflect natural spatial and temporal variability in the environment) and thus assure the quality of the data.

Data quality as a concept is meaningful only when it relates to the intended use of the data. That is, one must know the context in which the data will be interpreted in order to establish a relevant basis for judging whether or not the data set is adequate. DQA involves comparison of actual field and laboratory measurement performance to data quality objectives (DQOs) established for a particular study, such as evaluation of method detection limits, blank sample data, data precision (based on field and laboratory duplicate samples), and data accuracy (based on matrix spike recoveries and/or analysis of standards or certified reference materials). Only trusted and certified laboratories (e.g., analytical chemistry laboratories certified by Canadian Association for Laboratory Accreditation [CALA]) were involved in the SQIC and such certified laboratories have rigorous internal quality assurance programs that ensure the highest possible quality.

DQOs were established at the outset of the SQIC that reflect reasonable and achievable performance expectations. Programs involving a large number of samples and analytes usually yield some results that exceed the DQOs. This is particularly so for multi-element scans since the analytical conditions are not necessarily optimal for every element included in the scan. Generally, scan results may be considered acceptable if no more than 20% of the parameters fail to meet the DQOs. Overall, the intent of DQA is not to reject any measurement that did not meet a DQO, but to ensure that any questionable data received more scrutiny to determine what effect, if any, this had on interpretation of results within the context of this project.

C1.2 Types of Quality Control Samples

Several types of quality control (QC) samples were assessed based on samples collected (or prepared) in the field and laboratory. These samples include the following:

- **Blanks** are samples of de-ionized water and/or appropriate reagent(s) that are handled and analyzed the same way as regular samples. These samples will reflect any contamination that occurred in the field (in the case of field or trip blanks) or the laboratory (in the case of laboratory or method blanks). Analyte concentrations should be non-detectable, although a data quality objective of twice the method detection limit allows for slight “noise” around the detection limit.

- **Field Duplicates** are replicate samples collected from a randomly selected field station using identical collection and handling methods that are then analyzed separately in the laboratory. The duplicate samples are handled and analyzed in an identical manner in the laboratory. The data from field duplicate samples reflect natural variability, as well as the variability associated with sample collection methods, and therefore provide a measure of field precision.

- **Laboratory Duplicates** are replicate sub-samples created in the laboratory from randomly selected field samples which are sub-sampled and then analyzed independently using identical analytical methods. The laboratory duplicate sample results reflect any variability introduced during laboratory sample handling and analysis and thus provide a measure of laboratory precision.

- **Spike Recovery Samples** are created in the laboratory by adding a known amount/concentration of a given analyte (or mixture of analytes) to a randomly selected test sample previously divided to create two sub-samples. The spiked and regular sub-samples are then analyzed in an identical manner. The spike recovery represents the difference between the measured spike amount (total amount in spiked sample minus amount in original sample) relative to the known spike amount (as a percentage). Two types of spike recovery samples are commonly analyzed. Spiked blanks (or blank spikes) are created using laboratory control materials whereas matrix spikes are created using field-collected samples. The analysis of spiked samples provides an indication of the accuracy of analytical results.

- **Certified Reference Materials and QC Standards** are samples containing known chemical concentrations that are processed and analyzed along with batches of environmental samples. The sample results are then compared to target results to provide a measure of analytical accuracy. The results are reported as the percent of the known amount that was recovered in the analysis.

Two types of QC were applied to sediment toxicity testing as follows:

- **The Laboratory Control** test vessel(s) associated with sediment toxicity testing do not contain any of the material to be tested, rather are composed of sand augmented with the addition of a small amount of organic matter (peat moss). Organism survival and growth in the control vessel(s) are monitored and must show adequate survival and achieve a minimum weight at the end of the test.

- **Reference Toxicant Testing** involves conducting toxicity tests concurrent with the tests of field sediments using a toxicant for which the laboratory has developed limits. The results of the reference toxicant testing should fall within the developed limits. This testing ensures that internal test systems are in check and that the sensitivity of the test organisms is within an expected range.

Two types of QC were applied to benthic invertebrate community samples as follows:

- **Organism Recovery Checks** for benthic invertebrate community samples involve the re-processing of previously sorted material from a randomly selected sample to determine the number of invertebrates that were not recovered during the original sample processing. The reprocessing is conducted by an analyst not involved in the original processing to reduce any bias. This check allows the determination of accuracy through assessment of recovery efficiency.

- **Sub-Sampling Error** is assessed for studies in which benthic invertebrate community samples require sub-sampling (due to excessive sample volume and/or invertebrate density). By comparing the numbers of benthic invertebrates recovered between at least two sub-samples, this measure provides an evaluation of how effective the sub-sampling method was in evenly dividing the original sample. Therefore, sub-sampling error provides a measure of analytical precision. The processing of entire benthic invertebrate community samples in representative sample fractions also allows an evaluation of sub-sampling accuracy.

C2.0 WATER SAMPLES

C2.1 Method Detection Limits

Method detection limits (MDLs) were examined and assessed in all cases where sample results were reported as less than the MDL. For analytes for which a water quality guideline for the protection of aquatic life is available (Table C.1), the MDL should be lower than the guideline value.

All reported MDLs for both surface water and overlying water were lower than the guideline values (Table C.2).

All reported MDLs for sediment pore-water were lower than the guideline value with the exception of mercury (11 out of 50 samples; Table C.3). It is notable that mercury was not identified as a parameter of interest (POI) in the study and that water quality guidelines for the protection of aquatic life do not specifically apply to sediment pore-water. Therefore, the observed pore-water MDL greater than the mercury guideline for surface water does not impair data interpretability or study conclusions.

C2.2 Laboratory Blank Sample Analysis

More than 1,200 laboratory blank sample results were reported (Appendix J). In several instances, alkalinity was detected above the MDL in method blanks; however, in all cases, the associated sample results were at least five times greater than the blank levels and therefore the sample results were deemed reliable by the laboratory (Appendix J). Overall, this indicates no inadvertent contamination of samples within the laboratory during analysis.

C2.3 Field Blank Sample Analysis

A substantial number of field blanks were collected in association with surface water quality sampling and are reported elsewhere (Golder 2015). A single field blank sample was associated with sediment pore-water sampling. There was a detectable level of nitrate present in the sample (0.202 mg/L; Table C.4). Although this is an unusual result, it did not affect data interpretability or study conclusions. Although water quality guidelines for the protection of aquatic life do not apply to pore-water, this result was approximately 15-times below the guideline for nitrate in surface water. Furthermore, nitrate was not identified as an analyte of concern in a separate water quality impact assessment (Golder 2015). No other analytes were detectable in the field blank.

Table C.1: British Columbia water quality guidelines for the protection of aquatic life.

Analyte		Units	British Columbia Water Quality Guidelines [a]
Anions and Nutrients	pH	pH units	6.5 - 9.0

C2.4 Data Precision

Field Duplicate Samples

A substantial number of field duplicates were collected in association with surface water quality sampling and are reported elsewhere (Golder 2015). One duplicate water sample was collected in the field as part of the surface water sampling conducted to support benthic invertebrate community assessment of the Quesnel River. The duplicates showed excellent agreement in concentrations of all analytes except dissolved manganese (relative percent difference of 72.5%; Table C.5). Although the data quality objective of a relative percent difference (RPD) of ≤ 25% was not met for dissolved manganese, it was associated with a very low concentration (well below the range that would be of interest from the perspective of potential effects to aquatic life). RPDs for all other analytes were < 10%. Overall, the field duplicate sampling did not indicate any inconsistencies in sampling technique nor issue that could impair data interpretability.

Laboratory Duplicate Samples

A substantial number of laboratory duplicates were collected in association with surface water quality sampling and are reported elsewhere (Golder 2015). Forty laboratory duplicate analyses were associated with the pore-water samples and water samples collected to support the benthic invertebrate community assessment of the Quesnel River (Appendix J). In all cases where it was possible to calculate the relative percent difference (i.e., for all detectable results) samples met the objectives established by the laboratory, indicating excellent analytical precision.

C2.5 Data Accuracy

Over 900 analytical runs using certified reference materials were completed by the analytical laboratory and in all cases, objectives established by the laboratory were met (Appendix J). Similarly, over 1,000 results for matrix spike analyses were reported (Appendix J). In approximately 10% of the matrix spike results, the spike recovery could not be accurately calculated due to a high concentration of the analyte in the background sample. In all cases where spike recovery could be accurately calculated, recoveries met the objectives established by the laboratory (Appendix J). These data indicate excellent analytical accuracy associated with the water samples.

Table C.5: Relative percent difference (RPD) between field duplicate samples.
Highlighting indicates RPD that did not meet the objective of ≤ 25%.

[a] The method detection limit (MDL) value was used in instances where values less than the MDL were reported.
RPD calculation: =(Absolute(Replicate 1 - Replicate 2))/Average(Replicate 1, Replicate 2)*100

C2.6 Holding Time and General Laboratory Flags

Several hold times were exceeded due to the combination of short optimal hold times and remote sampling (Appendix J). Analytes for which recommended hold times were exceeded included nitrate/nitrite (3-day hold time), pH (15-minute hold time), dissolved phosphorus (3-day hold time), turbidity (3-day hold time), and dissolved orthophosphate (3-day hold time). Results associated with the hold time exceedences appear not to have been affected as they were comparable to those associated with samples where hold times were met.

There were few general laboratory flags associated with the water quality data (Appendix J). Two pore-water vials arrived at the lab either empty or broken and therefore the requested analysis (anions) could not be conducted on these samples.

C3.0 SEDIMENT SAMPLES

C3.1 Method Detection Limits

Method detection limits (MDLs) were examined and assessed in all cases where sample results were reported as less than the MDL. Target MDLs for sediment sample analyses were established at levels below all potentially applicable sediment quality guidelines (Tables C.6 to C.9). Target MDLs were met from most metals in most sediment quality datasets (Table C.6 to C.9). For "total" analytes in sediment (strong acid digestion), target MDLs were generally not achieved for lead, magnesium, manganese, molybdenum, selenium, silver, strontium, and tin (Table C.6). However, concentrations of lead, magnesium, manganese, strontium, and zinc were consistently greater than the lowest achievable MDL, and therefore data interpretation was not compromised for these analytes. Of the four remaining analytes (molybdenum, selenium, silver and tin), only selenium and silver have sediment quality guidelines and the achieved MDLs were at least 5-times lower than guideline. Furthermore, concentrations of molybdenum, selenium, silver and tin were greater than the MDL in 91%, 97%, 94% and 63% of all samples, respectively. Overall, MDLs achieved for the analysis of total metals in sediment were appropriate for the study and did not adversely affect data interpretability.

MDLs associated with sediment shakeflask analyses achieved targets in the majority of samples (Table C.7) and are therefore appropriate for this study. MDLs achieved in the selective extraction analyses (SEA or "Tessier" extractions) met the target MDLs for most metals and extractants (Table C.8). Higher rates of objective exceedance were observed for the following: 1) barium, molybdenum and silver in "exchangeable" extracts; 2) chromium and silver in the "carbonate" extracts; 3) silver in the "easily reducible and iron oxide" and "organic" extracts; and 4) arsenic, barium, chromium, manganese, nickel, silver, strontium and titanium in the "residual" extracts (Table C.8). The SEA is a specialized analysis and it is therefore not surprising that some MDLs, which were developed for more routine analyses, were not achieved. For data interpretation, SEA results were primarily used to provide perspective on the relative distribution of metals among extracts (or "phases") and, in very few cases did MDLs impair interpretation. Furthermore, SEA results were particularly important for copper, for which target MDLs were met in all extracts. Overall, the cases of achieved MDLs higher than target had only a small effect on data interpretability. Lastly, all MDLs achieved in the acid base accounting (ABA) analyses were suitable for project objectives (Table C.9).

Table C.6: Laboratory method detection limits (MDLs) for basic sediment chemistry analyses relative to targets and to guidelines. Only analytes with <MDL values are reported.

[a] British Columbia Water Quality Guidelines (BCMOE 2015a, 2015b); Chronic / Acute.

[b] Guideline value calculated using the mean leachable water hardness (137 mg/L) for applicable water bodies (Quesnel Lake, Quesnel River and Polley Lake) calculated using reported leachable calcium and magnesium concentrations.

[c] Applies to dissolved cadmium guideline.

[d] Applies to chromium as Cr (IV); guideline for Cr(III) is 0.0089 mg/L.

[e] Lowest mercury guideline value; MeHg = 0.5% of THg

Table C.8: Laboratory method detection limits (MDLs) for selectively extracted metals analyses in sediment samples (Tessier extractions) relative to targets and guidelines. Only analytes with <MDL values are reported. Bold and italicized values indicate target MDL based on guideline was not achieved.

[a] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b); TEL (Threshold or Lowest Effect Level) / PEL (Probable or Severe Effect Level).

Table C.9: Laboratory method detection limits (MDLs) for acid base accounting, sulphur, and carbon content analyses for sediment samples.

Parameter	Units	Achieved MDL Range	
		Lower	Upper
Maximum Potential Acidity (MPA)	$tCaCO_3$/1Kt	0.30 - 0.30	2,000 - 2,000
Fizz Rating	Unity	1.0 - 1.0	4.0 - 4.0
Net Neutralization Potential (NNP)	$tCaCO_3$/1Kt	1.0 - 1.0	1,000 - 1,000
pH	Unity	0.10 - 1.0	14.0 - 1,000
Neutralization Potential (NP)	$tCaCO_3$/1Kt	0.10 - 1.0	14.0 - 1,000
Neutralization Potential Ratio (NP/MPA)	Unity	0.010 - 0.010	1,000 - 1,000
Total Sulphur (S) - Leco	%	0.010 - 0.010	50 - 50
Sulphide Sulphur (S) - Calculated Leco	%	0.010 - 0.010	40 - 50
Sulphate Sulphur (S) - Carbonate Leach	%	0.010 - 0.010	40 - 50
Inorganic Carbon (C)	%	0.010 - 0.050	13.6 - 50
Carbon Dioxide (CO_2)	%	0.050 - 0.20	13.6 - 50
Sulphate Sulphur (S) - HCl leachable	%	0.010 - 0.20	50 - 50

C3.2 Laboratory Blank Sample Analysis

All of the laboratory blank results associated with the sediment analyses of non-metals, strong acid leachable metals, shakeflask extracted metals, SEA and ABA contained very low or non-detectable analyte concentrations (Appendix J). Only nine of approximately 2,370 blank samples associated with metals analysis failed to meet the DQO of less than or two-times the MDL (Appendix J); however, all associated sample results were at least five times greater than blank levels and are therefore considered reliable. Thirty-six of the approximately 3,200 (1%) method blank results associated with Tessier extractions failed to meet the DQO (Appendix J). Of these, about half were associated with sample results which were at least five-times greater than blank levels and are therefore considered reliable. For the rest, the Limits of Reporting were adjusted by the laboratory for samples with positive hits below five-times blank level (Appendix J). Consequently, these data are considered reliable. The method blank results for this study indicate no inadvertent contamination of samples within the laboratory during sediment analysis.

C3.3 Data Precision

Field Duplicate Samples

A total of 28 field duplicate sediment samples were collected for quality assurance (Tables C.10 to C.14). Evaluation of precision associated with sediment physical characteristics indicated good precision. Several instances of relative percent difference (RPD) greater than the objective of ≤ 40% RPD were observed for percent gravel or sand and total organic carbon content, but these were always at very low concentrations (Table C.10). Therefore, the precision associated with sediment physical analyses is suitable. Results for total sediment metals indicated excellent precision. In fact, there was only one case of RPD exceedence (mercury in sample QUL-47-03; Table C.11).

A number of cases of RPD > 40% were observed in the sediment shakeflask analyses (Table C.12). In all but one sample, these were limited to one or two analytes and RPD for manganese was greater than 40% in half of the field duplicates (Table C.12). In sample QUL-51-02, target RPD was exceeded for five analytes (calcium, iron, manganese, sodium and strontium), indicating poorer precision associated with this sample. Overall the precision associated with the shakeflask tests was poorer than for total sediment metals and appeared to be poorest for manganese. Conclusions based on manganese in shakeflask tests should consider the associated precision.

Table C.10: Field replicate results for the analysis of physical characteristics and non-metal parameters in sediment samples. Highlighted values did not meet the data quality objective of ≤ 40% Relative Percent Difference (RPD).

[a] The method detection limit (MDL) value was used in instances where values less than the MDL were reported. RPD calculation: =(Absolute(Replicate 1 - Replicate 2))/Average(Replicate 1, Replicate 2)*100

As with the analysis of total metals, field precision associated with the SEA results indicated good precision; there were few combinations of metal and extractant with precision that did not meet the target (Table C.13). Most exceedences occurred in a single set of duplicates (ST-02-S4), suggesting greater spatial variability at that location. In three instances, precision associated with copper analyes did not meet the objective: 1) "exchangeable and adsorbed" copper in replicates from POL-1-03M; 2) "easily reducible and iron oxide" copper in replicates from POL-2-04M; and 3) "carbonate" copper in replicates from ST02-S4 (Table C.13). Precision associated with the analyses of copper is of particular interest to the program because copper is the primary analyte affected by and indicative of mine influence. However, because the RPD exceedences occurred in only one of five samples in each case, it does not indicate a systematic issue and therefore does not adversely affect data interpretability. The observed variability likely represents real small scale differences in sediment (and sediment was particularly heterogeneous in Polley Lake). Lastly, field precision associated with the ABA testing was excellent in all samples but one – the duplicates collected at station POL-2-04P (Table C.14). At this station, neutralization potential, sulphide sulphur, inorganic carbon, carbon dioxide and sulphate sulphur all failed to meet the objective. It is notable that reducing conditions were observed at this station, which may have contributed to variability. Nonetheless, the result does not adversely affect data interpretation because neutralization potential ratios (NPR) were well above those at reference locations and well above levels considered indicative of acid generating potential.

Laboratory Duplicate Samples

All of the laboratory duplicate results associated with the sediment analyses of strong acid leachable metals, shakeflask extracted metals, SEA and ABA showed excellent agreement (Tables C.15 to C.19). Laboratory precision associated with the non-metals data (particle size, organic carbon and nitrogen) was excellent, meeting the data quality objective in all cases (Table C.15). In the strong acid leachable metal analyses, mercury and arsenic each failed to meet the objective (≤ 35% RPD) in only one out of 24 duplicate analyses (Table C.16), indicating excellent laboratory precision. Similarly, in the shakeflask analyses, only three instances of RPD exceedance were observed, and only one (iron in sample QUL-51-02) was particularly high (86%; Table C.17), indicating good analytical precision overall. In the SEA analyses, laboratory precision was also good, with few exceedances of the objective for laboratory precision observed, and with most of those in only two of 17 samples (Table C.18). Notably, none of the objective excedeences were for copper, the primary analyte affected by and indicative of mine

Table C.15: Laboratory duplicate results for the analysis of physical characteristics and non-metal parameters in sediment samples. Highlighted values did not meet the data quality objective of ≤ 35% Relative Percent Difference (RPD).

[a] RPDs were calculated by laboratory, see ALS Laboratory Reports in Appendix J
[b] Duplicate results outside ALS DQO due to sample heterogeneity.

Table C.18: Laboratory duplicate results for the analysis of selectively extracted metals in sediment samples (Tessier extractions). Highlighted values did not meet the data quality objective of ≤ 35% Relative Percent Difference (RPD).

[a] RPDs were calculated by laboratory, see ALS Laboratory Reports in Appendix J

[b] Duplicate results outside ALS DQO due to sample heterogeneity.

Table C.18: Laboratory duplicate results for the analysis of selectively extracted metals in sediment samples (Tessier extractions). Highlighted values did not meet the data quality objective of ≤ 35% Relative Percent Difference (RPD).

[a] RPDs were calculated by laboratory, see ALS Laboratory Reports in Appendix J
[b] Duplicate results outside ALS DQO due to sample heterogeneity.

Table C.18: Laboratory duplicate results for the analysis of selectively extracted metals in sediment samples (Tessier extractions). Highlighted values did not meet the data quality objective of ≤ 35% Relative Percent Difference (RPD).

[a] The method detection limit (MDL) value was used in instances where values less than the MDL were reported. RPD calculation: =(Absolute(Replicate 1 - Replicate 2))/Average(Replicate 1, Replicate 2)*100

influence. However, the laboratory failed to provide duplicate sample results for the easily reducible/iron oxide extracts. Laboratory precision associated with ABA was good, with exceedances of the objective restricted to sulphur determinations near the limit of analytical precision. Specifically, in all five instances where RPD was greater than the objective of 35%, the differences were by only one unit (Table C.19). Overall, laboratory precision achieved in this study was good and did not adversely affect data interpretability.

C3.4 Data Accuracy

Recoveries of all analytes in quality control standards associated with non-metals (approximately 210 analyses) and metals (approximately 6,800 metal results) met the respective DQOs (Appendix J). Thirty of the approximately 3,100 Tessier extraction metal results (<1%) failed to meet the laboratory's DQO for laboratory control samples (Appendix J). The analytical laboratory reported that the results are considered acceptable (Appendix J). Furthermore, barium, the only analyte which failed to meet the DQO, is not a parameter of interest or an indicator parameter in this study. Of the 305 QC Standard analyses associated with ABA analysis, the DQO was not met for only one inorganic carbon analysis and one carbon dioxide analysis (Appendix J). Recoveries of all leachable matrix spikes were also within the DQO range (Appendix J). Overall, these data indicate excellent analytical accuracy associated with the analysis of sediment samples.

C3.5 Holding Time and General Laboratory Flags

Most laboratory reports indicated no concerns as to the quality of the data reported. Several issues were flagged for sediment samples, largely relating to holding times that were exceeded for several analytes: pH, organic carbon, mercury, moisture content, total nitrogen (Appendix J). Hold times were exceeded for these analytes because the analytical laboratory did not complete all required analyses in the original run and were prompted for the additional data after initial data review. For one sample (from POL-2), shake flask metals and acid base accounting could not be completed due to limited sample volumes in sediment core sections. No issues were identified regarding the parameters of interest or indicator parameters associated with this study.

C4.0 SEDIMENT TOXICITY TESTING

C4.1 Laboratory Controls

Survival of both test organisms (*Hyalella azteca* and *Chironomus dilutus*) in laboratory controls met quality control objectives in all cases (>80% survival and >70% survival, respectively; Nautilus 2015 in Appendix J). Growth of *C. dilutus* met the quality control objective of ≥0.6 mg per individual at test completion; however growth of *H. azteca* did not quite meet the quality control objective of ≥0.1 mg per individual (Nautilus 2015 in Appendix J). Nautilus (2015) note that the *H. azteca* used in this testing typically grow to approximately 0.1 mg, but that growth in some controls was marginally lower (0.08 to 0.09 mg). The latter weights round to 0.1 mg, the level of measurement precision specified in the method. Furthermore, the laboratory ran mesh controls to determine if there was any evidence that control sediment was limiting growth. This investigation indicated that there was no evidence of growth limitation and therefore the laboratory concluded that the tests performed appropriately.

C4.2 Reference Toxicants

All reference toxicant testing results feel within the historical mean range (mean ± 2 standard deviations) and therefore the sensitivity of test organisms was considered to be appropriate.

C5.0 BENTHIC MACROINVERTEBRATE COMMUNITY SAMPLES

C5.1 Organism Recovery

The objective for percent organism recovery was met for all eleven samples that were re-sorted (Table C.20). Average recovery was 98.7%, compared to an acceptability objective of 90%. This indicates excellent organism recovery.

C5.2 Subsampling Precision

Due to modest benthic invertebrate densities, the majority of samples (93 of 111) were processed in their entirety (Table C.21). Evaluation of subsampling precision was completed on three of the 18 samples that were not processed in their entirety. All benthic invertebrate community sub-sampling met the DQO of 20%, with a precision range of 0.6 to 12.7% (Table C.22). This indicates excellent subsampling precision.

Table C.20: Benthic invertebrate community organism recovery. Highlighted values did not meet data quality objective of sort recoveries of ≥ 90%.

Sample ID	Number of Organisms Recovered (initial sort)	Number of Organisms in Re-sort	Percent Recovery

C6.0 BENTHIC MACROINVERTEBRATE TISSUE SAMPLES

C6.1 Method Detection Limits

Due to very small sample volumes, the achieved MDLs for benthic macroinvertebrate tissue samples did not always meet the target MDL (Table C.23). However, most analytes (19 of 25) were detected in the tissue samples and all six of the analytes that were not detected in tissue samples met their target MDL. Therefore, even though some target MDLs were not met due to small sample volumes, data interpretability was not affected.

C6.2 Laboratory Duplicate Samples

One replicate digest of a benthic invertebrate tissue sample and one replicate of an anonymous sample were prepared for analysis of laboratory precision. The data quality objective of ≤30% relative percent difference (RPD) was met for all analytes except aluminum, iron, lead, nickel, strontium, and vanadium (Table C.24). The absolute differences between duplicates for lead, strontium and vanadium were small, particularly considering that the concentrations were approaching the MDL (i.e., within ten-times the MDL). Furthermore, all of the RPDs were within laboratory limits, which the laboratory assesses on a case-by-case basis (Appendix J). Overall, relatively close agreement was achieved between laboratory duplicate samples indicating that reported sample results were associated with good analytical precision.

C6.3 Data Accuracy

Recoveries of all analytes in quality control standards run concurrent with the benthic macroinvertebrate tissue samples met the data quality objective of 70% -130% (Table C.25). These data indicate excellent analytical accuracy associated with the analysis of benthic invertebrate tissue samples.

Table C.23: Laboratory method detection limits (MDLs) for benthic invertebrate tissue sample analyses. Light grey highlighted values indicate target MDL was not achieved.

Analyte	Units	Target MDL	Achieved MDL Range			% of Achieved MDLs That Exceeded Either Target MDL

C7.0 DATA QUALITY STATEMENT

The quality of data for this project was generally good and was adequate to serve the project objectives. Any conclusions based on concentrations of mercury in sediment porewater and manganese in shakeflask tests should consider flags associated with the method detection limit and field precision, respectively. No other issues were identified that had the potential to affect data interpretability.

[1] Where in-situ measures were recoreded in the field on multiple sampling days or at multiple sampling depths, those recorded at the depth closest to the benthic sampling depth (bottom), and on the day that benthic sampling was completed are presented in this table.

Figure D.1: Habitat of sampled reference areas, Mount Polley Mine, Quesnel River Survey, October 2014.

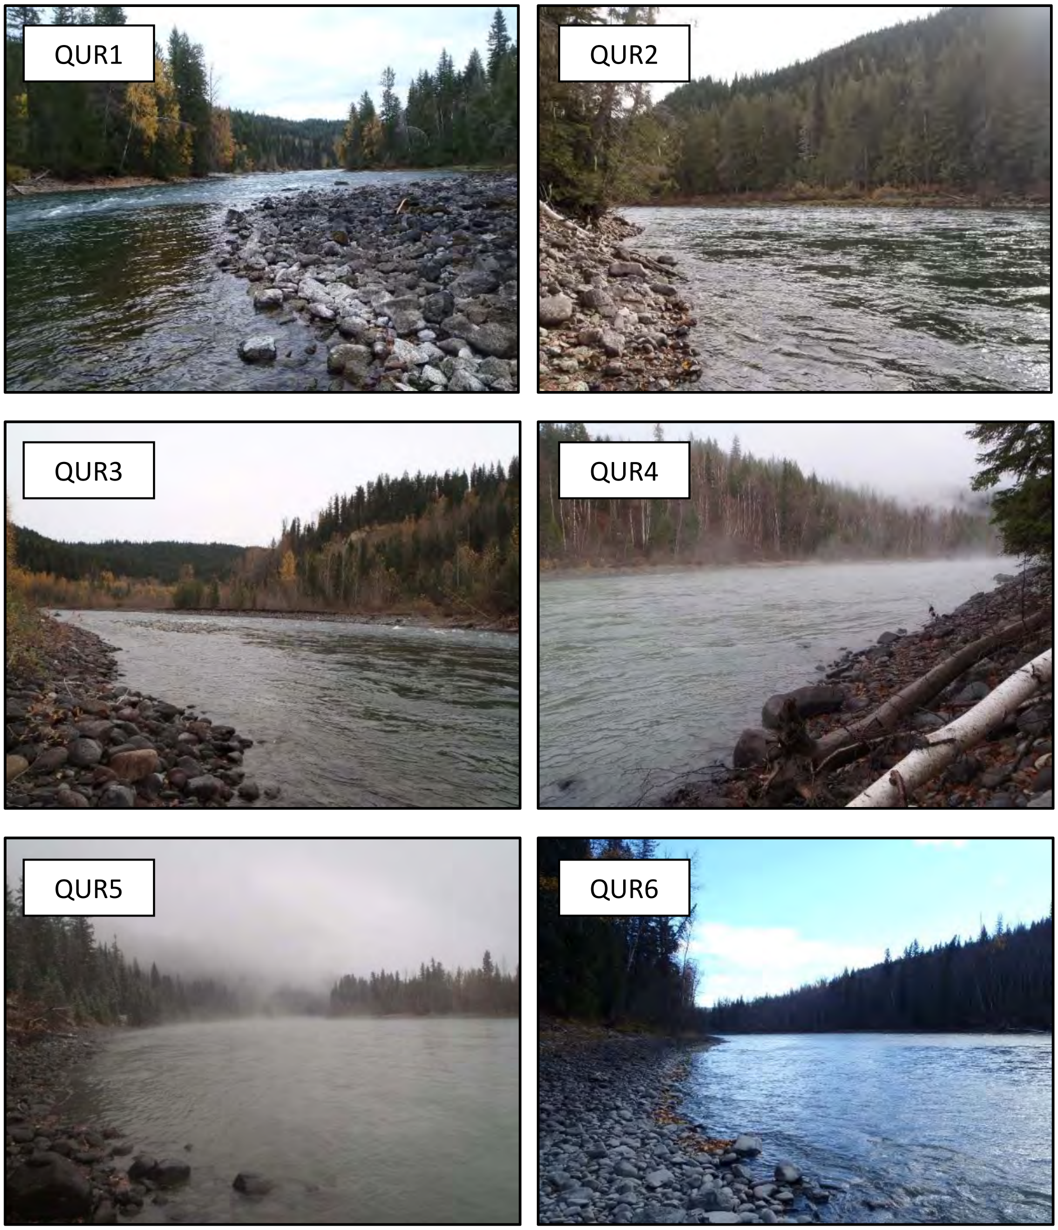

Figure D.2: Habitat of sampled mine-exposed areas along the Quesnel River, Mount Polley Mine,Quesnel River Survey, October 2014.

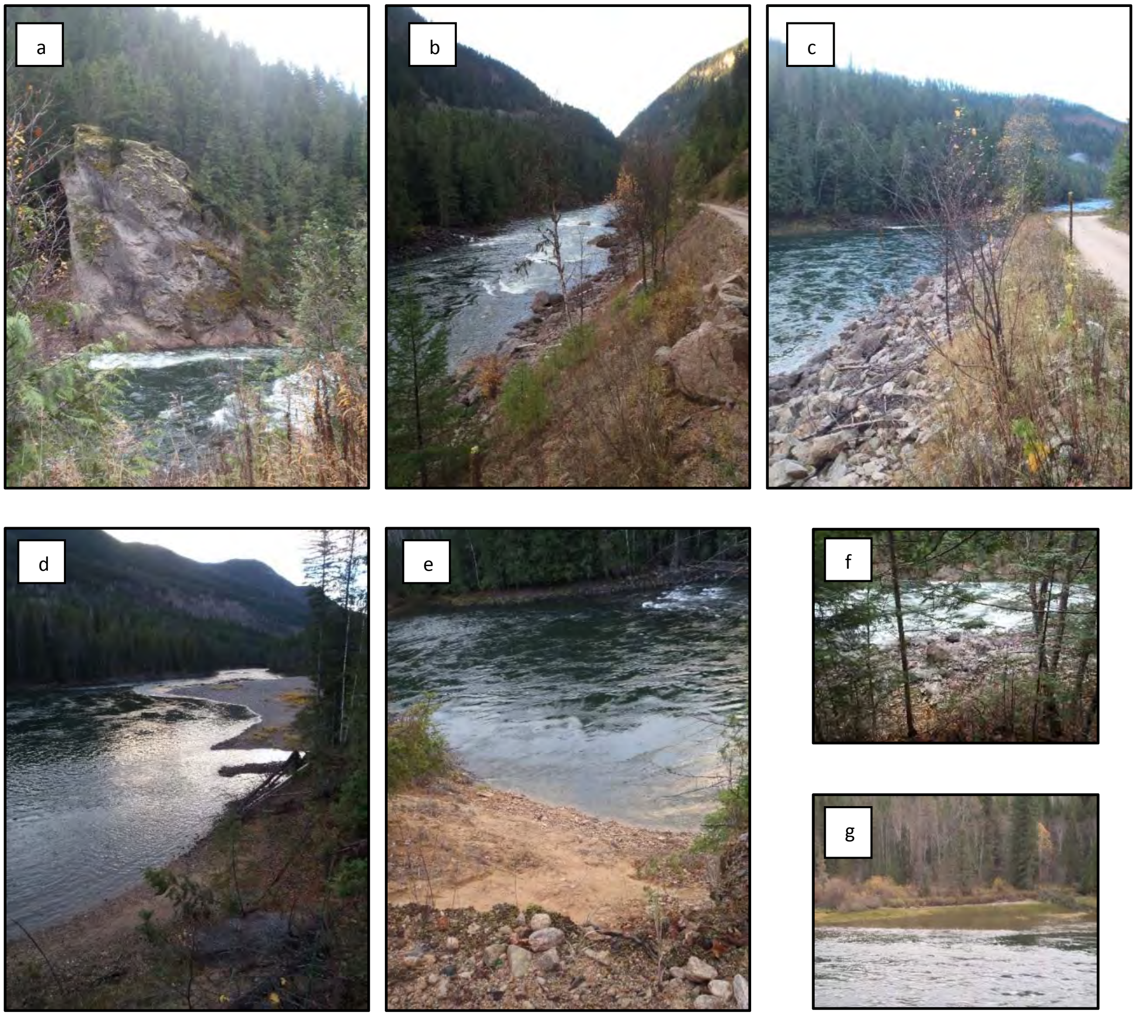

Figure D.3: Examples of unsuitable habitat on the Clearwater River, Mount Polley Mine, Quesnel River Study, October 2014 [1].

[1] A large extent of the Clearwater River was fairly channelized, with steep bedrock (a) or cobble/boulder (b, c, f) banks. At these areas, there was a steep drop-off which prevented kick sampling at 0.5 m deep, the velocity was far too fast (>0.3 m/s), and the substrate was often too large. One or two areas of the Clearwater River had cobble, however the substrate was smaller cobble with a large sand content than what was found on the Quesnel River. The water velocity was also far too high (d). A few areas were sandy with a steep and slumping bank (e). Two sections were observed that were slow-flowing back eddies with substrate that was either sandy/mucky or very small cobble (g).

[1] Reported TOC, TN, pH and moisture data are based on bulk sediment. Data < method detection limit (MDL) were used at the MDL for calculation of summary statistics. Means are reported as < MDL if all the data used in their calculation were < MDL.

[2] British Columbia Working Sediment Quality Guidelines (BCMOE 2015a, 2015b); TEL = Threshold (or Lowest) Effect Level; PEL = Probable (or Severe) Effect Level.

[3] Contaminated Sites Regulation (Government of British Columbia 1996).

[4] Historic sediment metal concentrations are based predominantly on bulk sediment samples.

(Blue) Value is > TEL. Values shown in bold text also exceed both upper and lower Hazeltine Creek Historic 95th Percentile values.

(Orange) Value is > PEL. Values shown in bold text also exceed both upper and lower Hazeltine Creek Historic 95th Percentile values.

Table E.1: Raw sediment quality data for Hazeltine Creek, Mount Polley Mine, 2014. Metals data are based on the <2mm fraction of sediment [1].
